Miscellaneous Scenarios

Summary

DIAGNOSTIC EVALUATION OF NEPHROLITHIASIS

Symptomatic urinary calculi are undoubtedly associated with significant patient discomfort. Despite the ability of many stones to pass spontaneously, the surgical treatments for calculi may themselves be morbid. Patients may suffer financial pain because of the expense of emergency department visits, office visits, surgical procedures, or time lost from work, in addition to the physical sequelae. Logically, most patients are interested in learning how to prevent a recurrence of such an episode. Through even a rudimentary understanding of the physiologic causes of urinary calculus formation, physicians may offer a straightforward approach to elucidating the metabolic basis of nephrolithiasis for any given patient. This evaluation should be simple to perform, it must be economically viable, and it should provide information that can be applied toward a selective, rational therapy of stone disease (Pak et al, 1980a).

Any evaluation should be able to identify associated metabolic disorders responsible for recurrent stone disease. These metabolic problems include distal renal tubular acidosis (RTA), primary hyperparathyroidism, enteric hyperoxaluria, cystinuria, and gouty diathesis. In many of these relatively uncommon conditions, it is generally agreed that selective medical therapy is indicated not only to prevent further stone formation but also to correct underlying physiologic disturbances that may lead to nonrenal complications (Pak et al, 2002a, 2003a).

Selection of Patients for Metabolic Evaluation

Debate continues regarding which patients require an extensive metabolic evaluation. First-time stone formers often have been estimated to have a 50% risk for recurrence within the subsequent 10 years (Uribarri et al, 1989). In two separate studies, Ljunghall and Danielson attempted to measure the incidence of a stone recurrence in a Northern European population (Ljunghall and Danielson, 1984; Ljunghall, 1987). A retrospective review estimated the chance of recurrence at nearly 50% at 5 years, whereas a prospective evaluation noted a lower overall rate of 53% within 8 years. Males had both a higher incidence of calculi overall and a higher recurrence rate. Patients had a higher risk for repeat stones in the years immediately after their first episode. It is not completely apparent whether these were preexisting stones that passed later or whether they represent the formation of new calculi.

In fact, recent evidence suggests that the prevalence of kidney stones has nearly doubled in the United States between 1994 and 2010 (Scales et al, 2012). Along with the overall increase in preva-

lence of kidney stones, there is an increasingly higher percentage of female stone formers (Scales et al, 2007). Other investigators have confirmed this finding with the reported ratio of male to female stone formers consistent between reports at 1.3:1 and 1.2:1 (Scales et al, 2007; Nowfar et al, 2011). In fact, the largest epidemiologic study to date suggests the male-to-female ratio of stone formers has now decreased to 1.45:1, not as a result of a decrease in male stone formation but as a significant increase in female stone formation (Pearle et al, 2005). This finding is thought to be due to changes in diet and lifestyle.

First-Time Stone Formers

Considering that dietary and fluid manipulation alone can reduce rates of stone recurrence, some suggest that first-time stone formers should be provided empirical fluid and dietary recommendations until they suffer a recurrence (Borghi et al, 1996). Indeed, studies of single-stone formers placed on a conservative program of high fluid intake alone or combined with avoidance of dietary excess, revealed a low incidence of recurrent stone disease (Hosking et al, 1983). Calling this finding the *stone clinic effect*, Hosking and colleagues noted metabolic inactivity in nearly 60% of all patients followed for over 5 years.

In comparison, Pak (1982) found that single-stone formers have an equally high incidence of metabolic abnormalities as recurrent stone formers. Furthermore, these derangements are just as severe, leading the authors to conclude that single-stone formers should undergo the same evaluation as recurrent stone formers. Similar findings were reported in a series of 182 patients, in which half of the patients had hypercalciuria or hyperuricosuria and roughly 20% had a systemic disorder that predisposed the patients to the formation of calculi (Strauss et al, 1982b). The remainder, 29.1%, had no metabolic disorder. Patients with single stones tended to be older when they passed their stones and required a greater rate of intervention to treat the calculus. The recurrence for both groups of patients was very similar (~10% at 3 years). Because the authors did not note substantial differences between solitary and recurrent stone disease, they recommended that first-time stone formers be evaluated similar to patients with recurrent stone disease. A more recent study comparing the frequencies of metabolic abnormalities between first-time stone formers and recurrent stone formers found no difference between the two groups (Eisner et al, 2012). Approximately 40% of both first-time and recurrent stone formers had hypercalciuria, 45% of both groups had hypocitraturia, and approximately 30% had hyperoxaluria. The authors suggest it is reasonable to perform a full metabolic evaluation in first-time stone formers.

This approach has been partially refuted by [Yagisawa and colleagues \(1998\)](#), who noted that men with recurrent calculi had a higher rate of metabolic derangements than first-time stone formers. Although women had a trend toward the same pattern, this achieved statistical significance only with regard to decreased levels of urinary citrate (hypocitraturia). A more complete discussion of the economic aspects surrounding the decision to perform a metabolic evaluation is found later in this chapter.

Importantly, the formation of a first stone may be the harbinger of a more severe underlying systemic disorder such as RTA, bone disease, or hypercalcemia resulting from hyperparathyroidism. In such patients, metabolic evaluation is justified solely to make the correct diagnosis to prevent extrarenal complications. With the development of reliable parathyroid hormone assays, it is unacceptable to wait for bone loss before embarking on curative therapy. Although the clinical significance of normocalcemic hyperparathyroidism has been questioned and is frequently simply observed, current practice favors the treatment of patients with at least 1 mg per deciliter above the upper limit of normal, marked hypercalciuria (urinary calcium excretion of more than 400 mg/day), reduced bone density, and an age of less than 50 years ([Bilezikian and Silverberg, 2004](#)).

The decision to thoroughly investigate a first-time stone former should ideally be shared by the physician and the patient. Whereas some first-time stone formers will readily accept and follow conservative therapy, others may elect to undergo a thorough evaluation. It is quite reasonable to determine the extent of evaluation according to the estimation of potential/risk for recurrent stone formation ([Smith, 1984](#)). Patients at higher risk for repeat episodes are those with a family history of stones and those with intestinal disease (particularly when causing chronic diarrheal states), pathologic skeletal fractures, osteoporosis, urinary tract infection (UTI), or gout. In these patients, an extensive evaluation is recommended. In addition, obese patients with stones, particularly obese women, have significantly elevated risk for recurrence and should be given consideration for metabolic evaluation ([Taylor et al, 2005](#)). Diabetes has been correlated with an increased risk for stone disease, and patients with diabetes and stones, particularly those with poorly controlled diabetes, should be considered for a full metabolic evaluation ([Weinberg et al, 2014](#)). Any patients with stones composed of cystine, uric acid, or struvite should undergo a complete metabolic workup.

All children should be required to undergo a complete investigation because they have been found to have a significant risk for underlying metabolic disturbances ([Polito et al, 2000](#); [Tekin et al, 2001](#); [Pietrow et al, 2002](#); [Coward et al, 2003](#); [Bartosh, 2004](#)). Pediatric patients with stones have a high rate of underlying metabolic abnormalities. Moreover, pediatric patients with metabolic abnormalities have been shown to have recurrence at a higher rate than those without metabolic risk factors ([Abhishek et al, 2013](#)). Additionally, these young patients have more at stake, because early, repeated episodes of urinary obstruction, UTI, and repeated radiographic imaging all have associated morbidities.

African-Americans previously have been observed to have a significantly lower incidence of nephrolithiasis than their white counterparts. Indeed, in a study by [Sarmina and colleagues \(1987\)](#), white patients had urinary calculi three to four times as often as black subjects. In contrast to findings of male predominance of stones in whites, [Michaels and associates \(1994\)](#) reported that women made up roughly 60% of the African-American patients with stones. [Sarmina and colleagues \(1987\)](#) found a higher incidence of infection calculi in the African-American population, whereas these stone types were excluded from analysis in the study by [Michaels and associates \(1994\)](#).

Additional support that race and ethnicity play a role in stone disease is provided by [Mente and coworkers \(2007\)](#). Compared to Europeans, East Asian and African patients had a decreased relative risk for calcium nephrolithiasis, and Arabic, West Indian, West Asian, and Latin American patients had an increased relative risk. The authors found differing urinary profiles for a variety of the ethnicities reported when compared to those of Europeans.

BOX 52-1 Indications for a Metabolic Stone Evaluation

Recurrent stone formers
Strong family history of stones
Intestinal disease (particularly chronic diarrhea)
Pathologic skeletal fractures
Osteoporosis
History of urinary tract infection with calculi
Personal history of gout
Infirm health (unable to tolerate repeat stone episodes)
Solitary kidney
Anatomic abnormalities
Renal insufficiency
Stones composed of cystine, uric acid, struvite

However, despite the decreased risk for calcium stone formation, patients of African ancestry demonstrated no significant differences in urinary metabolic derangements. A more recent study looking at the prevalence of stones in the United States between 2007 and 2010 found a significantly lower rate of stones for African-Americans, Hispanics, and multiracial persons compared to that in whites ([Scales et al, 2012](#)). Although the prevalence of stones in African-Americans remained lower than in whites, the increase in stone prevalence from the previous report (1988 to 1994) to the current report (2007 to 2010) was over 150%.

Following the assumption that a lower incidence of calculi might imply a significant risk for a metabolic or anatomic abnormality in patients who still manage to make calculi, it seems reasonable to advocate for the performance of a metabolic evaluation for all patients of African-American descent. This suggestion is supported by recent studies that assessed the underlying metabolic abnormalities of nonwhite stone formers. African-Americans, Asians, and Hispanics appear to have a surprisingly similar incidence of underlying metabolic disturbances when compared with white stone formers. These results suggest that dietary and environmental factors may be as important as ethnicity in the cause of stone disease ([Beukes et al, 1987](#); [Maloney et al, 2005](#)).

Regardless of whether a particular patient requires a full metabolic evaluation, it is prudent to perform at least a screening evaluation combined with a thorough history and physical examination to assess for underlying systemic syndromes that may cause recurrent calculi and extrarenal complications. This assessment also should screen for patients at an increased risk for stone recurrence, as outlined in the previous paragraphs ([Box 52-1](#)).

KEY POINTS: SELECTION OF PATIENTS FOR METABOLIC EVALUATION

- The incidence of nephrolithiasis is increasing.
- The historic male predominance of stone formers is disappearing.
- Racial “protection” may be overcome by dietary indiscretions.
- Children should generally be evaluated because of concerns about renal damage and long-term sequelae of stone recurrence.

Abbreviated Protocol for Low-Risk Single-Stone Formers

In single-stone formers without increased risk for recurrence, the following abbreviated protocol may be applied ([Box 52-2](#)). A thorough medical history should be obtained for any underlying conditions that may have contributed to the stone disease. Because of the association between bowel disease and calcium oxalate nephrolithiasis (enteric hyperoxaluria), a careful history of bowel habits

BOX 52-2 Abbreviated Evaluation of Single-Stone Formers**History**Underlying predisposing conditions (as per [Box 52-1](#))

Medications (calcium, vitamin C, vitamin D, acetazolamide, steroids)

Dietary excesses, inadequate fluid intake, excessive fluid loss

Multichannel blood screen

Basic metabolic panel (sodium, potassium, chloride, carbon dioxide, blood urea nitrogen, creatinine)

Calcium

Intact parathyroid hormone

Uric acid

Urine**Urinalysis**

pH > 7.5: infection lithiasis

pH < 5.5: uric acid lithiasis

Sediment for crystalluria

Urine culture

Urea-splitting organisms: suggestive of infection lithiasis

Qualitative cystine**Radiography**

Radiopaque stones: calcium oxalate, calcium phosphate, magnesium ammonium phosphate (struvite), cystine.

Radiolucent stones: uric acid, xanthine, triamterene

Intravenous pyelogram: radiolucent stones, anatomic abnormalities

Stone analysis

and bowel disease should be sought ([Smith et al, 1972](#); [Bohles et al, 1988](#); [Lindsjo et al, 1989](#); [McConnell et al, 2002](#); [Worcester, 2002](#); [Parks et al, 2003b](#)). This includes questions regarding chronic diarrhea that could be caused by inflammatory bowel disease (Crohn disease, ulcerative colitis) or irritable bowel syndrome. A history of gout should be sought, because this finding may predispose the patient to hyperuricosuria or gouty diathesis with either uric acid calculi or calcium oxalate stone formation ([Grover and Ryall, 1994](#); [Khatchadourian et al, 1995](#); [Kramer and Curhan, 2002](#)). As described by [Pak and colleagues \(2003c\)](#), patients with a history of diabetes mellitus may be at an increased risk for developing a gouty diathesis, with altered ammonium management, acidic urine, and a predisposition for a mixture of calcium oxalate and/or uric acid stones.

A thorough surgical history should be obtained focusing particularly on bariatric surgery and surgeries on the intestinal tract. Roux-en-Y gastric bypass surgery has been shown to significantly increase the risk for kidney stones ([Matlaga et al, 2009](#)). This study demonstrated a significantly higher rate of stones in obese patients who underwent gastric bypass surgery compared to obese patients who had not (7.65% vs. 4.63%). In contrast to gastric bypass surgery, restrictive bariatric surgeries such as gastric sleeve or gastric band do not seem to increase the risk for kidney stone formation ([Chen et al, 2013](#)). Bowel resection, particularly of the small intestines, can lead to malabsorption with an increased risk for kidney stone formation, and patients with prior bowel surgery should be considered for a metabolic evaluation.

In addition, information should be obtained concerning the patient's dietary habits, including fluid consumption and excessive intake of certain foods, as well as a list of all medications taken. A social history may provide obvious clues regarding a patient's hydration status. Does the patient have access to fluids on a regular basis? Does the patient perform daily tasks that would increase the insensible losses of fluids? Patients on prolonged bed-rest demonstrate alterations in urinary chemistry such that urinary calcium and phosphorus excretion increase significantly, leading to

significant increases in urinary saturation of calcium phosphate, calcium oxalate, and monosodium urate, particularly during bed-rest ([Hwang et al, 1988](#)). A family history may reveal a genetic predisposition to urinary calculi if there is a history of close relatives affected by nephrolithiasis. Age of onset of the patient or of affected relatives may give clues regarding genetic disorders such as autosomal recessive cystinuria.

A multichannel blood screen is helpful in identifying certain systemic problems. These include primary hyperparathyroidism (high serum calcium and low serum phosphorus), renal phosphate leak (hypophosphatemia), uric acid lithiasis (hyperuricemia), and distal RTA (hypokalemia, decreased serum carbon dioxide).

Voided urine specimens should be obtained for comprehensive urinalysis and culture. The urinalysis should include pH determination (preferably with an electrode), because a pH greater than 7.0 is suggestive of infection lithiasis or RTA, whereas a pH less than 5.5 suggests uric acid lithiasis secondary to gouty diathesis.

The urine sediment should be examined for crystalluria, because particular crystal types may give a clue as to the composition of stones the patient is forming. Tetrahedral "envelopes" are seen in calcium oxalate lithiasis ([Fig. 52-1](#)), and rectangular, "coffin-lid" crystals are often seen in patients with struvite calculi (see [Fig. 52-1](#)). Hexagonal crystals confirm cystinuria (see [Fig. 52-1](#)); uric acid crystals may be seen as amorphous fibers or as irregular plates. The microscopic appearances of common calculi are summarized in [Table 52-1](#).

Urine cultures are performed if there is a suspicion of infection-related calculi or if there are signs or symptoms of a UTI. A culture that is positive for urea-splitting organisms such as *Proteus*, *Pseudomonas*, *Klebsiella*, *Staphylococcus aureus*, and *Staphylococcus epidermidis* would help explain the formation of a struvite calculus. A positive culture also will warrant therapy with appropriate antibiotics before initiation of any surgical procedure to remove the stone. The surgical management of a calculus during an active infection will place the patient in great risk for bacteremia or sepsis. **Unfortunately, many infected calculi will harbor bacteria even after treatment with broad-spectrum antibiotics.** [Korets and colleagues \(2011\)](#) evaluated the concordance between preoperative bladder urine cultures with renal pelvic urine cultures and stone cultures in patients undergoing percutaneous nephrolithotomy. They found that despite treatment with culture-specific antibiotics, stone culture was positive in 17 patients (8.6%) who had a positive preoperative bladder urine culture. Another 16 patients had a positive stone culture associated with a negative preoperative bladder culture. Furthermore, [McAleer and associates \(2003\)](#) demonstrated that infection calculi contain large quantities of endotoxin after disintegration. In a comparison of infected versus noninfected calculi, infected stones contained 36 times more endotoxin. Half of the infected calculi grew bacterial cultures that were different from the preoperative urine specimens. The same investigators described how endotoxin can cause a vascular collapse because it induces physiologic changes consistent with those of septic shock ([McAleer et al, 2002](#)).

Abdominal x-ray films (kidney-ureter-bladder [KUB]) should be obtained to document the existence of any current stones within the urinary tract. The radiopacity of any existing stones may suggest the type of stones present. Although magnesium ammonium phosphate and cystine stones are often radiopaque, they are not as dense as calcium oxalate or calcium phosphate stones. A plain abdominal film is also useful in identifying nephrocalcinosis (suggestive of RTA). A noncontrast computed tomography (NCCT) scan may be obtained to confirm the presence of radiolucent stones and also identify any anatomic abnormalities that may predispose the patient to stone formation. It is important to realize that the radiographic evaluation of a patient during a metabolic workup of stone disease will differ from an approach taken during an episode of acute renal colic. In an acute stone episode, the majority of patients will be examined with NCCT, which is able to quickly image the entire collecting system in a rapid sequence ([Fig. 52-2](#)) ([Smith et al, 1995](#); [Sommer et al, 1995](#); [Katz et al, 1996](#); [Fielding et al, 1997](#); [Freed et al, 1998](#)).

Figure 52-1. Scanning electron micrographs of various urinary crystals. A, Apatite. B, Struvite. C, Calcium oxalate dehydrate. D, Calcium oxalate monohydrate. E, Cystine. F, Ammonium acid urate. G, Brushite. (Courtesy Dr. S.R. Khan, University of Florida, Gainesville, FL.)

In patients who are seen for metabolic evaluation, an NCCT may not be justified because of concerns regarding cost and radiation exposure. Digital tomosynthesis is a promising new imaging technology that may be useful for the evaluation and follow-up of patients with recurrent stones. It is performed with a plain abdominal radiograph and a single tomographic sweep of the x-ray emitter. Multiple coronal slice images are then reconstructed by digital software. Digital tomosynthesis has been shown to have improved sensitivity over that of plain KUB for the detection of renal stones

and significantly less radiation than an NCCT (Mermuys et al, 2010; Neisius et al, 2014).

Finally, available stones should be analyzed to determine their crystalline composition. The presence of uric acid or cystine would suggest the presence of a gouty diathesis or cystinuria, respectively. The finding of struvite, carbonate apatite, and magnesium ammonium phosphate would suggest infection lithiasis. A predominance of a hydroxyapatite component suggests the presence of RTA or primary hyperparathyroidism and warrants an assessment of basic

electrolytes. Stones composed of pure calcium oxalate or mixed calcium oxalate and hydroxyapatite are less useful diagnostically because they may occur in several entities, including absorptive and renal hypercalciuria, hyperuricosuric calcium nephrolithiasis, enteric hyperoxaluria, hypocitraturic calcium nephrolithiasis, and low urine volume (Kourambas et al, 2001; Pak et al, 2004).

Figure 52-2. Computed tomography image of a urinary calculus. All stones (with the exception of some medication calculi) appear as dense, white objects (arrow) within the urinary collecting system.

KEY POINTS: ABBREVIATED PROTOCOL FOR LOW-RISK SINGLE-STONE FORMERS

- A complete medical history should be obtained from all stone formers.
- Patients should be screened for medical diseases that predispose to calculi.
- Serum metabolic panel and urinalysis tests should be performed.
- Urine microscopy for crystals may provide clues to diagnosis.
- Stone analysis may improve the accuracy of further evaluation.
- Basic radiography (plain films) should screen for existing calculi.

Extensive Diagnostic Evaluation

A more extensive evaluation, directed at the identification of underlying physiologic derangements, should be performed in patients with recurrent nephrolithiasis as well as in stone formers at increased risk for further stone formation.

Pak and colleagues (1980a) initially described an extensive outpatient (ambulatory) evaluation in 1980 and subsequently made minor revisions to help simplify the process (Levy et al, 1995). The basic strategy involves two outpatient visits, and most of the required laboratory analyses can be performed in a routine clinical laboratory, with only a few of the specialized techniques being performed in a more sophisticated laboratory. The entire schedule of visits and tests is outlined in Table 52-2.

Before and throughout the period of evaluation, the patient is instructed to discontinue any medication known to interfere with the metabolism of calcium, uric acid, or oxalate. These medications include vitamin D, calcium supplements, antacids, diuretics, acetazolamide, and vitamin C. Any current medication for stone treatment (thiazides, phosphate, allopurinol, or magnesium) should be discontinued as well, to better determine the patient’s baseline physiology (and pathophysiology). Two random 24-hour urine samples are collected. These 24-hour specimens are obtained with the patient on a random diet, which is reflective of their usual dietary intake. It is important to stress to the patient to maintain their normal diet and fluid intake during urine collections. An attempt on the patient’s part to suddenly eat well or to increase fluid consumption for the sake of the test will only mask the underlying causes of the stone disease.

Most patients will require detailed instructions on the proper collection of a complete 24-hour urine specimen. The patient

TABLE 52-1 Microscopic Appearance of Common Urinary Calculi

CHEMICAL TYPE	APPEARANCE
Calcium oxalate monohydrate	Hourglass
Calcium oxalate dihydrate	Envelope, tetrahedral

should choose a day when all voids can be completely captured and when the specimen will represent a typical day. The first morning void is discarded, because this represents urine from the previous night and may not have had a predictable starting point. From that point on, all urine must be collected in the appropriate, laboratory-provided container. The canister may need to be kept on ice and/or preservatives should have been added according to the requirements of the specific laboratory. When the patient awakens the next morning, the first morning void is collected with the rest of the specimen, thereby completing a full 24 hours. Total urinary creatinine should be measured to provide an internal check. Males will be expected to have produced roughly 20 to 25 mg of creatinine for every kilogram of body weight during the 24-hour period. Females generally have less muscle mass and therefore will typically produce 15 to 20 mg of creatinine for every kilogram of body weight in 24 hours. Significant aberrations in total creatinine excretion from these estimated values imply incomplete collection, overcollection, greater than expected muscle mass, or less than expected muscle mass.

In the past, a third 24-hour sample was collected after 1 week with the patient on a diet restricting calcium, sodium, and oxalate. This dietary restriction was imposed to standardize the diagnostic tests, to better assess the cause of hypercalciuria (i.e., absorptive hypercalciuria I vs. absorptive hypercalciuria II), and to prepare for the “fast and calcium load” test, which was performed on the second visit. Blood samples are obtained as outlined in Table 52-2.

Fast and Calcium Load Test

Because of the similar treatment of patients with absorptive hypercalciuria and renal leak, the performance of fast and calcium load testing is no longer performed by most clinicians. With very little therapeutic distinction, there is not much of an incentive to discriminate between the two types of hypercalciuria. However, differentiation between absorptive hypercalciuria and renal hypercalciuria is mainly of historical interest because the treatment for both is the same (see Selective Medical Therapy of Nephrolithiasis, later in this chapter). When new, more targeted medications are developed, this distinction will be clinically applicable. A description of the fast and calcium load study is included here primarily for completeness and historical purposes.

A fast and calcium load study may be performed on the morning of the second visit (Pak et al, 1975). The purpose of this exercise is to help delineate between various causes of hypercalciuria. As explained in Chapter 51 in greater detail, some patients are too efficient at absorbing calcium from the intestinal tract (absorptive hypercalciuria I and II), whereas others suffer from a constant loss of calcium from the renal tubules (renal calcium leak). A third subset of patients has an overabundance of circulating parathyroid hormone, usually from a single parathyroid adenoma, and has a constant loss of calcium and phosphate (resorptive hypercalciuria or primary hyperthyroidism, respectively).

To differentiate among these three hypercalciuric subtypes, it is essential that the patients have adhered to the restricted diet for at least 7 days before this testing so as to eliminate the effects of absorbed calcium on fasting calcium excretion. To ensure adequate hydration, distilled water (300 mL each) is taken 12 hours and 9 hours before the calcium loading. Other than water ingestion at these time periods, the patients are to be fasting. Two hours before the scheduled calcium loading, patients empty their bladder completely, discard this urine, and drink an additional 600 mL of distilled water. All urine produced over the next 2 hours is collected as a pooled sample before taking an oral calcium load (fasting urine). After the 2-hour fasting urine collection has been completed, a 1-g oral calcium load is administered using 250 mL of a liquid synthetic diet (Calcitest) as a carrier solution. This synthetic “meal” is prepared by adding 500 mL of water to a can of Calcitest. Because 250 mL of the synthetic meal contains only 100 mg of calcium, 39 mL of Neo-Calglucon (900 mg of calcium) must be added to bring the total calcium up to 1 g. The final mixture should be taken slowly over a 5- to 10-minute period.

For the next 4 hours, urine is again collected as a pooled sample (postload urine). Both fasting and postload samples are then assayed for calcium and creatinine. Fasting urinary calcium is expressed as milligrams per deciliter glomerular filtrate (GF) because it is reflective of renal function. To obtain this unit of measurement, the urinary calcium in milligram per milligram creatinine is multiplied by the serum creatinine in milligram per deciliter. Normal fasting urinary calcium is less than 0.11 mg/dL GF. The postload urinary calcium is best expressed as milligram per milligram creatinine because it is a function of a fixed oral calcium load. The normal value for this measurement is less than 0.2 mg calcium/mg creatinine.

KEY POINTS: EXTENSIVE DIAGNOSTIC EVALUATION

- A complete metabolic evaluation may be obtained as an outpatient.
- Calcium fast and load tests can discriminate between the various forms of hypercalciuria.
- Routine performance of calcium fast and load tests is not required to complete a metabolic evaluation.

Simplified Metabolic Evaluation

The previously described extensive ambulatory protocol affords the physician a high diagnostic yield and is quite reliable. Unfortunately, many practicing physicians have found this protocol to be time-consuming and difficult to perform because of the inability to find a reliable local laboratory or perceived complexities of the evaluation protocol. Indeed, the full evaluation does entail several office visits and requires strict adherence to fluid protocols during the calcium fast and load tests.

Several authors have suggested a more simplified approach that uses the same standard principles and procedures as the full outpatient evaluation. These simplified protocols do not include the calcium fast and loading tests and may not require adherence to a restricted diet, permitting them to be performed in a single office visit. Rivers and colleagues (2000) recommend the collection of two separate 24-hour urine specimens. One is collected while on a restricted diet, and the other allows a random (typical) diet. Such manipulation is well tolerated by the patient and may allow for identification of the various types of hypercalciuria with reasonable certainty.

Pak (1997) recognized the cumbersome nature of an extensive evaluation and made similar recommendations. Based on the findings of a single 24-hour urine collection, patients are evaluated and treated without all steps of fasting and loading calcium challenges. Patients are separated into complicated and uncomplicated calcium stone disease, based on the presence or absence of normocalcemia, normouricemia, and calcium stones and the absence of UTI, bowel disease, or marked hyperoxaluria. Comprising the majority of all patients, uncomplicated calcium stone disease is further separated into a hypercalciuric group and a normocalciuric group. Medical therapy is then based on this distinction.

Lifshitz and colleagues (1999) advocated for a less complex approach. All patients undergo a basic metabolic screening, searching for systemic disorders that could pose a long-term health risk. They suggest that all patients should be advised about conservative nonspecific preventive measures. Patients at high risk for forming stones should have a more extensive metabolic evaluation based on two 24-hour urine samples.

The cornerstone of these simplified protocols has been the development of a urine preservation method that allows collection of urine without refrigeration. The patient is then able to submit an aliquot to a central laboratory for the analysis of various stone-forming substances (Nicar et al, 1987). The urinary constituents most commonly assayed include calcium, oxalate, citrate, total volume, sodium, magnesium, potassium, pH, uric acid, and sulfate. Although most of these parameters are self-evident, sulfate is added to the list to assess the volume of protein loading from animal meat.

From such determinations, the urinary saturation with respect to stone-forming salts can be calculated.

At present, multiple laboratories offer services focused on simplified, accurate 24-hour urine assessment for stone-forming risk factors. These laboratories provide collection containers with chemical preservatives (obviating iced storage and transport) and extrapolate 24-hour cumulative data from the submission of a small aliquot of the entire collection. After the values of all urinary constituents and saturations have been determined, the physician receives a computer printout that provides a numeric display of the test results (Fig. 52-3). A graphic display of this information also may be generated, highlighting the increased or reduced risk for each environmental, metabolic, or physicochemical factor (Fig. 52-4). These results should aid the physician in formulating a metabolic/physiologic diagnosis. It may be difficult to make a definitive diagnosis on a single 24-hour urinalysis; therefore repeated evaluation is often warranted. For example, it is desirable to confirm the presence of hypocitraturia or hyperuricosuria by repeat measurements.

Controversy exists regarding the necessity of collecting two separate 24-hour urine specimens. As noted earlier, Rivers and colleagues (2000) advocated for the collection of two samples while the patient is on differing diets (random and restricted). Assuming that the patient complies, these data may be used to discern between

absorptive hypercalciuria II and renal leak (hypercalciuria disappears while the patient is on the restricted diet in absorptive hypercalciuria II). Researchers from Dallas suggest that only a single 24-hour collection is required (Pak et al, 2001). Their study retrospectively reviewed and compared the results of two 24-hour urine samples that were collected on random diets. They noted no significant difference in the excretion of urinary calcium, oxalate, uric acid, citrate, pH, total volume, sodium, potassium, sulfate, or phosphorus. They concluded that the reproducibility of urinary stone risk factors was adequate in repeat samples, enough so that therapy would not have been altered.

Conversely, Parks and colleagues (2002) noted significant disparities between two separate collections. Over 1000 patients were examined from both private practice and academic settings. They noted that within nearly 70% of the comparisons, there were large enough differences that the standard deviation would contain clinically relevant disparities. The authors therefore conclude that relying on one specimen alone could easily lead to misdiagnosis and, consequently, mismanagement.

Finally, it is important to note that the "normal limits" cited on commercially available urine analysis packages may not be the same as normal values quoted previously. Therefore close attention should be paid to patients who may fall in the gray zone when using a commercially available urine analysis package.

KEY POINTS: SIMPLIFIED METABOLIC EVALUATION

- A simplified metabolic evaluation of nephrolithiasis has been established.
- Commercial laboratories may facilitate the collection of 24-hour urine studies.
- There is no consensus regarding the need for one versus two 24-hour urine collections during an initial evaluation (although we prefer two random collections).

USE OF STONE ANALYSIS TO DETERMINE METABOLIC ABNORMALITIES

Questions have arisen regarding the necessity of both chemical stone analysis and metabolic evaluation for patients with nephrolithiasis. **Although stone composition analysis is neither always feasible nor desirable, there is helpful information from such an investigation that can aid with preventive therapy.** Unfortunately, chemical and mineralogic names of common calculi are sometimes used interchangeably, causing significant confusion for the clinician. A list of these names is provided in [Table 52-3](#).

[Parks and colleagues \(1997\)](#) demonstrated that a given patient's supersaturation of urinary crystals coincides with the stones produced by the patient. Indeed, in their study, treatments that reduced stone rates also reduced the supersaturation values of the

TABLE 52-3 Mineralogic Names of Renal Calculi

Calcium oxalate dihydrate	Weddellite
Calcium hydrogen phosphate dihydrate	Brushite
Tricalcium phosphate	Whitlockite
Carbonite-apatite	Carbonite-apatite
Magnesium ammonium phosphate	Struvite
Cystine	None
Uric acid	None

historical stone composition for that patient. If calculi develop as a result of prolonged supersaturation of various crystals (e.g., calcium oxalate, urate), it is further reassuring that "snapshot," pooled urine supersaturation measurements accurately track stone admixtures and are a reliable index of long-term, "average" renal and urine supersaturations.

Assessment of stone composition, not just urinary crystal supersaturation, can be a helpful adjunct to a metabolic evaluation. **Because most stones are a mixture of more than one component, the relative ratios or predominance of any particular molecule may have predictive value.** In an analysis of almost 1400 patients who had both stone analysis and a complete metabolic evaluation,

[Pak and colleagues \(2003b\)](#) noted that calcium apatite and mixed calcium oxalate–calcium apatite stones were associated with the diagnoses of RTA and primary hyperparathyroidism (odds ratios [OR], ≥ 2), but not with chronic diarrheal syndromes. As the phosphate content of the stone increased from calcium oxalate to mixed calcium oxalate–calcium apatite, and finally to calcium apatite, the percentage of patients with RTA increased from 5% to 39%, and those with primary hyperparathyroidism increased from 2% to 10%. Not surprisingly, pure and mixed uric acid stones were strongly associated with a gouty diathesis and brushite stones were associated with RTA. As expected, a very strong association was found between infection stones and infection and between cystine stones and cystinuria.

These findings were further supported by [Kourambas and colleagues \(2001\)](#). Stone composition correlated with metabolic findings in a series of 100 consecutive patients. A significant risk for RTA was documented in patients producing predominantly calcium phosphate calculi. Kourambas and colleagues maintain that the finding of a noncalcareous stone simplifies the evaluation by focusing the ensuing workup on the most obvious cause. Pure uric calculi are primarily a result of gouty diathesis, and these patients may not require further testing.

Finally, [Lingeman and associates \(1995\)](#) noted that the finding of pure struvite/calcium apatite in a staghorn calculus predicted a low likelihood of finding other metabolic abnormalities during a workup. In their series, only 2 of 14 with pure infection stones had additional abnormalities compared to 7 of 7 patients with mixed chemical compositions. They therefore suggest that patients with pure infection stones will not benefit from additional evaluation. In a more recent report, metabolic abnormalities were found in 3 of 5 patients with pure struvite stones and 17 of 22 with mixed struvite stones ([Iqbal et al, 2013](#)). This suggests that in patients with pure struvite stones, a metabolic evaluation should be considered to aid in stone prevention.

KEY POINTS: USE OF STONE ANALYSIS TO DETERMINE METABOLIC ABNORMALITIES

- Stone analysis may obviate the need for a complete metabolic evaluation.
- Stone composition can direct metabolic investigation.

ROLE OF IMAGING IN DETERMINING STONE COMPOSITION

Radiologic imaging is mainly used for determination of the presence or absence of calculi, renal anatomy, and associated findings (i.e., hydronephrosis). Thus diagnostic imaging plays a crucial role in the surgical planning and follow-up of patients with nephrolithiasis. Aside from the inability to identify pure uric acid stones on plain radiography compared to computed tomography (CT), diagnostic imaging has not historically proved to be beneficial in the medical evaluation and management of stone disease.

Accompanying the ubiquity and increased utility of CT imaging, a number of authors have sought to identify characteristics by stone composition that could be determined from this diagnostic modality ([Mitcheson et al, 1983](#); [Newhouse et al, 1984](#); [Mostafavi et al, 1998](#); [Nakada et al, 2000](#); [Saw et al, 2000](#); [Motley et al, 2001](#); [Bellin et al, 2004](#); [Deveci et al, 2004](#); [Sheir et al, 2005](#)). These investigations focused on Hounsfield unit (HU) measurements to determine stone composition. Both in vitro and in vivo work demonstrated significant differences in HU between pure uric acid stones and other stone types. However, it has been more difficult to differentiate pure struvite from cystine, calcium oxalate from brushite, and stones of mixed composition. Because of the significant variance in the readings obtained for different stone types, even with optimization of standard CT variables (collimation, pitch), this information has been of little clinical value.

More recently, the application of dual-energy CT (DECT) technology is demonstrating the potential to better characterize stone type. In vitro studies using ratios of HU during DECT have been able to distinguish among uric acid, calcium phosphate, and calcium oxalate calculi ([Matlaga et al, 2008](#)). Further discrimination of stone composition has been reported by two other sets of investigators. [Boll and associates \(2009\)](#), using an alternative calculation method, showed graphical separation of relatively pure cystine, struvite, calcium oxalate, calcium phosphate, and brushite stones. This group's "DECTslope" algorithm identified stone compositions unambiguously; however, separation of calcium oxalate and calcium phosphate calculi was not obtained. In an in vivo study, this same group was able to successfully identify stone composition and differentiate calcium oxalate from brushite stones ([Zilberman et al, 2010](#)). [Grosjean and colleagues \(2008\)](#) further characterized uric acid, cystine, struvite, calcium oxalate dihydrate, brushite, and calcium oxalate monohydrate into distinct groups with the use of DECT attenuation values. The ability to differentiate stone composition was noted to be lost when the image was subjected to respiratory motion artifact. [Primak and coworkers \(2007\)](#) used commercially available software to differentiate uric acid stones from non-uric acid stones. They were able to demonstrate 100% accuracy in differentiating between uric acid and non-uric acid stones. The exception was in an obese model, in which accuracy decreased to 92%. Early work with DECT is promising but must be confirmed in vivo before incorporation into clinical decision making for the metabolic evaluation and medical management of nephrolithiasis.

ECONOMICS OF METABOLIC EVALUATION

There is no doubt that the costs associated with the treatment of nephrolithiasis are substantial. In 1984, [Shuster and Scheaffer](#) estimated that the average stone episode cost approximately \$2000, exclusive of recurrences. At the time, this finding was based on a predominance of open surgical approaches with an average hospital stay lasting 4 to 5 days. The average annual cost of recurrence for a current stone case was conservatively estimated to be in the range of \$300 to \$400. Based on these conservative projections, they estimated that the entire national population of white males in the age range of 18 to 60 years yielded an annual cost because of kidney stones approaching \$315,000,000 ([Shuster and Scheaffer, 1984](#)).

By 1993 the estimated costs continued to climb, despite advances in technology and decreases in inpatient care. Indeed, [Clark and associates \(1995\)](#) performed a review of prevalence data for urolithiasis and the relative frequency of surgical treatments from Civilian Health and Medical Program of the Uniformed Services claims data. They found that the total annual cost for the evaluation and management of nephrolithiasis to be \$1.83 billion in the United States alone.

At the onset of the new millennium, the economic burden of urolithiasis continued to rise. Estimations of the annual medical expenditures for stone disease in the United States for 2000 were \$2.1 billion, inclusive of \$971 million for inpatient services, \$607 million for physician office and hospital-based outpatient services, and \$490 million for emergency room charges ([Pearle et al, 2005](#)). These calculations are based on a range of nationally available datasets and do not necessarily reflect the additional societal costs of lost productivity and social service support. These costs are clearly not negligible because the peak incidence of urolithiasis occurs in patients between 20 and 60 years of age (the years of highest workers' productivity) and an analysis of more than 300,000 beneficiaries from 25 large U.S. employers identified that 30% of patients with urolithiasis missed an average of 19 hours of work and had an additional \$3500 in annual medical costs ([Saigal et al, 2005](#)).

With the increasing incidence of stone disease, it only can be concluded that the national health care expenditure for urolithiasis will continue to rise. Particularly worrisome is the increasing evidence that obesity confers an increased risk for nephrolithiasis,

which is quite sobering considering the epidemic of obesity that is enveloping the United States (Curhan et al, 1998a; Ekeruo et al, 2004; Morrill and Chinn, 2004; Rigby et al, 2004; Strumpf, 2004; Taylor et al, 2005; Scales et al, 2012).

With these figures in mind, prudence would dictate that medical prevention could help curb runaway costs and prevent long-term sequelae of recurrent nephrolithiasis. The emergence and instant appeal of shock wave lithotripsy and improved endoscopy in the mid-1980s prompted some authors to remind the urologic community that medical assessment was still a viable option (Resnick and Pak, 1987; Preminger, 1994). However, office visits, serum studies, and 24-hour urine studies have their own costs. Is there a break-even point at which the costs of a metabolic evaluation, pharmacologic prophylaxis, and continued office visits are less than the expense of surgical management?

Chandhoke (2002) compared the cost of medical prophylaxis with the cost of clinically managing recurrent stone episodes. Additionally, he determined the stone recurrence rate without prophylaxis (stone frequency) at which these two treatment approaches became cost equivalent. This review conducted a cost survey in 10 countries to compare costs of medical prophylaxis and managing recurrent acute stone episodes. Costs of an acute stone episode included an emergency department visit, associated radiographic imaging to confirm diagnosis of a symptomatic stone, and outpatient treatment of upper urinary tract stones that did not pass spontaneously. Costs of medical management included an initial limited metabolic evaluation, drug therapy, a follow-up office visit every 6 months that included a 24-hour urinalysis, and yearly radiographic KUB imaging. Not surprisingly, the costs of medical prophylaxis and managing an acute stone episode varied significantly from country to country. The stone frequency at which costs of these management options became equivalent ranged from 0.3 to 4 stone episodes per year. This study concluded that medical management of a first stone episode is not cost-effective and that individual decisions should be determined by local costs.

Researchers at the University of Texas, Southwestern Medical Center have created a decision tree model to evaluate the cost-effectiveness and stone recurrence rates of common management strategies in stone formers (Lotan et al, 2004). They evaluated four common medical strategies: dietary measures alone (conservative), empirical drug treatment, or directed drug therapy based on simple or comprehensive metabolic evaluation. The model made reasonable assumptions regarding costs for evaluation, medications, emergency treatment, and surgery for stone recurrence. A review of the literature guided estimations of stone recurrence and risk reduction from various medical therapies. They found that first-time stone formers were best treated with a conservative approach because it was the least costly and it yielded a stone formation rate of 0.07 stone per patient yearly. For recurrent stone formers, conservative treatment was less costly than drug treatments but it was associated with a higher stone recurrence rate (0.3 stone per patient yearly). Directed medical therapies were more costly than conservative treatment (\$885 to \$1187 vs. \$258 yearly), but they provided the obvious advantage of decreasing recurrence rates by 60% to 86%.

The authors went on to compare the expense of the simple medical evaluation and associated management as described earlier in this chapter and noted it to be more costly than empirical treatment but also more effective. Importantly, a complete evaluation with attendant treatment offered no advantage in cost or efficacy over empirical treatment or modified simple metabolic evaluation and management. The authors also recommended that first-time stone formers be treated with conservative therapy because it is both cost-effective and efficacious. In contrast, however, recurrent stone formers should be treated medically after a simplified evaluation, because of the high recurrence rate of stone formation. Despite the recommendation for recurrent stone formers to undergo a simplified evaluation, Milose and colleagues found that in 2006 only 7.9% of high-risk stone formers were evaluated with 24-hour urine collections (Milose et al, 2013).

KEY POINTS: ECONOMICS OF METABOLIC EVALUATION

- Routine performance of a comprehensive metabolic evaluation may not be economically sound if applied to all stone patients.
- Many first-time stone formers may not benefit economically from a metabolic evaluation unless initial screening puts them in a high-risk category.
- Recurrent stone formers are best treated with a metabolic evaluation and directed medical therapy.

CLASSIFICATION OF NEPHROLITHIASIS AND DIAGNOSTIC CRITERIA

Using an ambulatory protocol, the cause of nephrolithiasis can be classified into 12 separate categories reflecting specific physiologic derangements. The details regarding the physiology and pathophysiology of these distinct entities are included in Chapter 51. These categories are listed in Table 52-4, along with the relative frequency of their occurrence as noted by Pak and colleagues at a dedicated Stone Clinic in an academic medical center (Levy et al, 1995). An argument can be made that these relative incidences may not be representative of the general population for two reasons. First, referral to an academic center may imply a more serious version of stone disease and may therefore represent a selection bias. Second, recognizing that there are at least some regional variations of stone incidence (Harvey et al, 1990), this particular patient population may be distinctly different from those in a different region of the United States or other regions of the world.

Calcium-Based Calculi

Hypercalciuria (>200 mg/day)

Absorptive Hypercalciuria. The classification of nephrolithiasis recognizes three broad categories of hypercalciuria. Absorptive hypercalciuria involves an increase in the amount of calcium absorbed by the intestinal tract. In absorptive hypercalciuria I, this increased absorption will occur regardless of the amount of calcium in the patient's diet. Therefore these subjects will demonstrate an increased urinary excretion of calcium on both the fasting and the loading specimens. In contrast, patients with absorptive hypercalciuria II will have a normal amount of urinary calcium excretion during calcium restriction, but will show elevations during their regular diet. Patients with both subtypes of absorptive hypercalciuria will have normal serum calcium and a normal level of circulating intact parathyroid hormone (iPTH). In fact, these patients often demonstrate a low iPTH because of suppression from a constant abundance of available serum calcium.

Renal Hypercalciuria. Renal hypercalciuria (also known as renal leak hypercalciuria) is thought to be due to a wasting of calcium by the functioning nephron. The details of this process and various hypotheses are outlined in Chapter 51. As a result of constant loss of calcium from the distal tubules, these patients will demonstrate hypercalciuria during all phases of fasting, loading, or restricting of dietary calcium. Most patients with renal hypercalciuria will have a normal serum calcium, but may exhibit a mild elevation of iPTH as the regulatory systems attempt to keep up with the constant loss of calcium.

Resorptive Hypercalciuria (Primary Hyperparathyroidism). Patients with resorptive hypercalciuria suffer from an overproduction of parathyroid hormone from either one dominant adenoma or diffuse hyperplasia of all four glands. The hallmark of this disorder is the persistence of increased urinary calcium during all parts of the dietary calcium manipulations. In addition, these patients frequently demonstrate hypercalcemia and elevations of the parathyroid hormone. The measurement of only the iPTH

has avoided confusion from the measurement of fragments of the same molecule (Kao et al, 1982; Nussbaum et al, 1987) and has greatly enhanced the ability to make this diagnosis.

Unfortunately, some patients may have normocalcemic hyperparathyroidism. These patients may be hard to distinguish from those with renal leak hypercalciuria, during which serum calcium will be normal but a mild elevation of the iPTH can occur, creating a secondary hyperparathyroidism. In these instances the patients can be treated with a 2-week course of a thiazide diuretic, such as chlorthalidone 25 mg daily. If the patient actually has renal leak, the calcium loss should be suppressed and the iPTH should return to normal (Aroldi et al, 1979; Barilla and Pak, 1979; Zechner et al, 1981). Those with true primary hyperparathyroidism will continue to circulate elevated levels of iPTH and may become mildly hypercalcemic, although this latter feature has been debated in the literature (Klimiuk et al, 1981; Farquhar et al, 1990; Strong et al, 1991).

Idiopathic Hypercalciuria. Idiopathic hypercalciuria can be found in both normal people and stone formers (Coe et al, 1979). These patients may demonstrate elevated amounts of urine calcium in all phases of the dietary calcium manipulation, but will not demonstrate serum abnormalities. **On a cautionary note, this term does not always enjoy a strict definition and is sometimes sub-**

TABLE 52-5 Differential Diagnosis of Hypercalciuria

	ABSORPTIVE	RENAL	RESORPTIVE
Serum calcium	Normal	Normal	Elevated

Intestinal calcium absorption	Elevated (primarily)	Elevated (secondarily)	Elevated (secondarily)

stituted to describe patients with hypercalciuria who have not undergone further evaluation to discriminate among the various subcategories. Although this diagnosis is not as “clean” as possible, it represents a more pragmatic approach to hypercalciuria, because the treatment for absorptive and renal hypercalciuria is often the same (as outlined later in this chapter). Table 52-5 summarizes the laboratory parameters that help delineate the various types of hypercalciuria.

KEY POINTS: HYPERCALCIURIA

- Hypercalciuria can be divided into three causes: excessive gastrointestinal (GI) absorption, renal tubular leak, hyperparathyroidism.
- Idiopathic hypercalciuria refers to unevaluated or unknown cause.

Hyperuricosuric Calcium Oxalate Nephrolithiasis

Patients with hyperuricosuria may be prone to the formation of calcium oxalate calculi through the process of heterogeneous nucleation (also referred to as epitaxy) (Coe and Kavalach, 1974; Pak and Arnold, 1975; Coe, 1980). The details of this process are outlined in Chapter 51. These patients give a history of calcium oxalate nephrolithiasis and may have a history of hyperuricemia with symptomatic gout. During metabolic evaluation, these patients will demonstrate hyperuricosuria (>800 mg/day).

Hyperoxaluria (>40 mg/day)

Enteric Hyperoxaluria. This entity is often one of the most striking findings during a metabolic evaluation because it involves multiple factors, all caused as a result of chronic diarrhea with its attendant dehydration and bicarbonate losses (Worcester 2002). The main hallmark is, of course, hyperoxaluria with values that can be quite high (i.e., > 50 mg/day). As a result of intestinal fluid loss, patients will often exhibit low urine volumes. The bicarbonate loss (and the consumption of citrate as an acid/base buffer) also can cause a low urine pH and hypocitraturia (Rudman et al, 1980). Urine calcium excretion is often low because of the saponification of oral calcium with poorly absorbed fats in the intestinal tract.

Primary Hyperoxaluria. Primary hyperoxaluria is an extremely rare disorder caused by an inborn error of metabolism. The more common variant, type 1, is due to a defect of the enzyme alanine glyoxylate aminotransferase (AGT) via an autosomal recessive inheritance. Type 2 is a less common variant thought secondary to a defect in D-glycerate dehydrogenase, which has both glyoxylate and hydroxypyruvate reductase. Primary hyperoxaluria usually manifests during childhood with early stone formation, tissue

deposition of oxalate (oxalosis), and renal failure resulting from nephrocalcinosis. Death often occurs before age 20 in untreated patients (Williams and Smith, 1968; Leumann and Hoppe 1999). Metabolic evaluation will reveal high urine oxalate excretion and high serum levels of this molecule.

Mild Metabolic Hyperoxaluria (Dietary). The importance of dietary oxalate and the possibility of an inheritable sensitivity to oral oxalate loads are debated and are discussed in Chapter 51. It appears increasingly evident that a deficiency of a bacterium found within intestinal flora (*Oxalobacter formigenes*) is a factor in the formation of calcium oxalate calculi (Allison et al, 1986; Sidhu et al, 1999; Troxel et al, 2003; Siener et al, 2013). In some patients, the cause of *Oxalobacter* deficiency may be iatrogenic because it is sensitive to a number of commonly prescribed antibiotics, including ciprofloxacin and levofloxacin (Lange et al, 2012). Regardless of the underlying cause, some patients without primary hyperoxaluria or without a history of bowel disorders will demonstrate an elevation of oxalate in 24-hour urine collection. A review of the patient's dietary habits may reveal a predisposition for foods that are particularly high in oxalate. **Although this molecule is ubiquitous and cannot be avoided, certain foods can deliver substantial amounts of oxalate in one serving.** Box 52-3 presents an abbreviated list of foodstuff that are particularly high in oxalate (Assimos and Holmes, 2000; Holmes and Assimos, 2004). A recent pilot study suggests that compliance with dietary modifications to reduce oxalate intake can be improved with an interactive Internet program (Lange et al, 2013).

Hypocitraturic Calcium Nephrolithiasis (<550 mg, Female; <450 mg, Male)

There is some controversy regarding the definition of normal urinary citrate excretion. Women tend to have higher urinary citrate measurements than men, particularly before menopause (Pak, 1990). Despite noting gender differences, Pak (1990) and colleagues define normal urine citrate as greater than 320 mg for both genders. In some of the earlier studies from Dallas, hypocitraturia was found in up to 50% of all patients evaluated, frequently in association with other abnormalities (Nicar et al, 1983). Parks and Coe (1986) also noted the importance of urinary citrate for the prevention of calcareous stones and have set the limits of normal at higher values, with men being more than 450 mg and women at more than 550 mg daily. Nevertheless, hypocitraturia is considered one of the more common metabolic diagnoses, probably second only to hypercalciuria. There are four causes of hypocitraturia, as described in the following section.

Distal Renal Tubular Acidosis (Type 1). Patients may have either an acquired or an inheritable version of RTA, with the incomplete version representing a less serious clinical pattern. Regardless of the actual cause, the laboratory hallmark of this disease is a low urine citrate (hypocitraturia) with an inappropriately high urine pH (Wang and Preminger, 2011). Often, the measured 24-hour urine citrate will be quite diminished, with values less than 100 mg/day. The urine pH will be elevated to 6.5 or above. Hypokalemia is often evident on the serum studies, as is hyperchloremia. A non-anion gap acidosis may be present as well

with carbon dioxide values in the mid-teens (Preminger et al, 1985). First void urine samples can be evaluated to assess the urine pH and screen for RTA. Patients with RTA will be unable to acidify urine overnight and should have a urine pH no lower than 5.5.

Distal RTA may manifest as an isolated entity, or it may be the secondary manifestation of a variety of systemic and renal disorders. More than two thirds of patients with distal RTA are adults, but occasionally children will be identified with this disorder. Infants generally present with vomiting or diarrhea, failure to thrive, and growth retardation; children often present with metabolic bone disease and renal stones; and adults frequently present with symptoms attributable to nephrolithiasis and nephrocalcinosis.

Up to 70% of adults with distal RTA have kidney stones (Caruana and Buckalew, 1988). Those patients with onset at an early age or with severe forms of the disorder may develop nephrocalcinosis and eventual renal insufficiency (Fig. 52-5). RTA is more common in women, accounting for nearly 80% of all cases. It is very important to note that secondary RTA can be induced by many common urologic disorders that also may be sought after a diagnosis of acquired RTA. These include obstructive uropathy, pyelonephritis, acute tubular necrosis, renal transplantation, analgesic nephropathy, sarcoidosis, idiopathic hypercalciuria, and primary hyperparathyroidism and can lead to secondary RTA (Buckalew, 1989) (Box 52-4).

Some patients will have an incomplete variant of the disease with less marked hypocitraturia and a more normal urine pH level.

Figure 52-5. Computed tomography (CT) (A) and plain film (B) of a patient with renal tubular acidosis and renal failure. Both kidneys demonstrate severe calcification of the medullary pyramids consistent with nephrocalcinosis. Note the atrophic left kidney on the CT image (A).

BOX 52-3 Foods Containing High Levels of Oxalate

Tea (black)	Okra
Cocoa	Berries (some)
Spinach	Chocolate
Mustard greens	Nuts
Pokeweed	Wheat germ
Swiss chard	Soy crackers
Beets	Pepper
Rhubarb	

BOX 52-4 Causes of Acquired Renal Tubular Acidosis

Obstructive uropathy
 Recurrent pyelonephritis
 Acute tubular necrosis
 Renal transplantation
 Analgesic nephropathy
 Sarcoidosis
 Idiopathic hypercalciuria
 Primary hyperparathyroidism

Incomplete variants can be diagnosed with the use of an ammonium chloride loading challenge. In this evaluation, the fasting patient is given 0.1 g of ammonium chloride per kilogram of body weight in crushed granules mixed with a soft drink. Subsequently, hourly measurements of urinary pH and bi-hourly measurements of serum pH or bicarbonate are taken over 4 to 6 hours (Pohlman et al, 1984). If the serum pH falls below 7.32, or the bicarbonate falls below 16 mmol/L but urinary pH remains at or above 5.5, the diagnosis of incomplete distal RTA is confirmed. If at any time the urinary pH falls below 5.5, the diagnosis of incomplete distal RTA is excluded (Preminger et al, 1985, 1987, 1988).

Chronic Diarrheal States. The laboratory findings in a patient with a chronic diarrheal disorder are similar to those in patients with enteric hyperoxaluria. However, these patients do not tend to suffer from the bowel inflammation and subsequent heightened permeability to oxalate. Therefore urinary oxalate may be mildly elevated, but usually not to the extent as found in patients with bowel resection or inflammatory disorders. These patients likely will demonstrate moderate decreases in urinary citrate excretion with associated low urine volumes (Fegan et al, 1992; Caudarella et al, 1993; Worcester, 2002; Parks et al, 2003b).

Thiazide-Induced Hypocitraturia. One of the side effects of thiazide therapy is the development of hypocitraturia. This defect is presumably secondary to the hypokalemia and resultant intracellular acidosis that may develop after prolonged therapy with thiazides (Pak et al, 1985b). Because thiazides are still widely used as a diuretic and for the management of hypertension, some patients may present with a stone episode after prolonged therapy with this medication. Stone patients who are treated with thiazides for the control of hypercalciuria should be screened for hypocitraturia (Pak et al, 1985b).

Idiopathic Hypocitraturia. Patients with idiopathic hypocitraturia include all those with 24-hour urine citrate less than 550 mg (males) or 450 mg (female) in the absence of any of the previously noted disease states. It is important to consider unrecognized incomplete RTA as a potential diagnosis, because this disorder carries with it a significant risk for long-term morbidity. Additionally, a careful history should be taken to screen for bowel dysfunction.

KEY POINTS: HYPOCITRATURIA

- The definition of hypocitraturia may vary greatly.
- Severe hypocitraturia should immediately raise suspicions for RTA.
- Hypocitraturia frequently accompanies other diagnostic categories.

Hypomagnesuric Calcium Nephrolithiasis (<80 mg)

Hypomagnesuric calcium nephrolithiasis is characterized by low urinary magnesium, hypocitraturia, and low urine volume. It is frequently associated with chronic thiazide therapy (Ljunghall et al, 1981; Preminger et al, 1989). More commonly, inflammatory bowel disorders, particularly those that cause malabsorption, have

been implicated in this process (Preminger et al, 1989). Excessive dependence on laxatives may induce a pattern similar to chronic diarrheal states (Dick et al, 1990; Soble et al, 1999). The importance of this disorder has been questioned, however, with the suggestion that the stone-risk association of hypomagnesuria may actually be due to its effect on urinary citrate (Schwartz et al, 2001).

Uric Acid–Based Calculi**Gouty Diathesis**

The pathophysiology of uric acid nephrolithiasis is explained in detail in Chapter 51 but does deserve some mention to better understand its diagnosis. Because there are no known inhibitors of uric acid crystallization, undissociated uric acid will precipitate when the urine becomes supersaturated. The sigmoidal-shaped solubility curve will predict that at a pH of 6.5 more than 90% of all uric acid is ionized and therefore soluble. Fifty percent of uric acid will be soluble at a pH of roughly 5.5 (pK_a) (Gutman and Yu, 1968). By definition, patients with gouty diathesis have a urine pH of less than 5.5.

It follows, then, that patients with gouty diathesis and uric acid calculi tend to have lower urine pH than normal subjects (Gutman and Yu 1968). Measurements of this molecule at 24 hours often will be greater than 800 mg. Up to 20% of patients with gout will develop uric acid calculi, prompting examination of serum for hyperuricemia. Often, 24-hour urine collections can underestimate the total amount of uric acid if the specimen pH drops lower than 5.5. In this scenario, the uric acid forms precipitates and settles to the bottom of the collection container.

It should not be difficult to distinguish between patients with hyperuricosuric calcium nephrolithiasis (HUCN), who form calcium oxalate stones, and those with gouty diathesis, who can form either uric acid or calcium oxalate calculi. Patients with HUCN present with normal urinary pH and hyperuricosuria, accompanied sometimes by hypercalciuria. In contrast, those with gouty diathesis have a low fractional excretion of urate (that contributes to hyperuricemia) and low urinary pH (that leads to increased amount of undissociated uric acid) (Khatchadourian et al, 1995; Pak et al, 2003c). The varying biochemical and physicochemical presentations of the two conditions can be ascribed to overindulgence with purine-rich foods in those with HUCN and underlying primary gout in those with gouty diathesis (Pak et al, 2002b).

A dietary history should be obtained from all patients with uric acid calculi, because they may have a tendency to purine gluttony (high intake of animal protein). An astute clinician will at least give a brief consideration to the possibility of a neoplastic or myeloproliferative disorder. Patients with diabetes mellitus also may form uric acid calculi as a result of disorders in ammonium handling with subsequent low urine pH (Pak et al, 2003c; Eisner et al, 2010b).

Uric acid calculi can be notoriously radiolucent. Tomography may overcome this difficulty (Fig. 52-6), as can the acquisition of an NCCT scan. DECT can be used to distinguish uric acid calculi from calcium stones with a high degree of accuracy (Primak et al, 2007). These stones frequently have an orange appearance, especially when viewed endoscopically. Uric acid–stone formers can have a propensity to produce large volumes of very small calculi that may cause obstruction as they pass down the ureter.

KEY POINTS: URIC ACID–BASED CALCULI

- Hyperuricosuria may be associated with pure uric acid calculi or calcium oxalate calculi.
- Patients with gout may be predisposed to uric acid stones.
- Dietary indiscretion (purine gluttony) should always be suspected.

Figure 52-6. A, Plain film tomographic appearance of a lower pole partial staghorn uric acid calculus (arrows). B, The addition of intravenous contrast demonstrates the stone as a “filling defect” (arrows) during the excretory portion of the intravenous pyelogram.

Cystinuria

Cystinuria is caused by an autosomal recessive error of transepithelial transport involving the intestine and kidneys (Thier et al, 1965; Pak and Fuller, 1983). In this disease, patients are unable to reabsorb the dibasic amino acids: cystine, ornithine, lysine, and arginine. The resultant accumulation of cystine causes crystallization when concentrations rise above the saturation point (~ 250 mg cystine per liter of urine) (Pak and Fuller, 1983).

Patients with this disorder may present at a young age and may have affected first-degree relatives. The stones are often yellow and waxy and are relatively faint on plain radiography. Staghorn calculi or multiple, filled calyces are common (Fig. 52-7).

Historically, a diagnosis of cystinuria was made with the use of a sodium nitroprusside spot test that turned purple in the presence of cystine (Smith, 1977). Although this test is a helpful screening adjunct, quantitative measurements of cystine can be difficult to perform because of interference from other sulfhydryl-containing compounds (such as medications used to treat this disorder) or from significant variances with minor changes in urine pH or creatinine content (Pak and Fuller, 1983). Coe and colleagues (2001) developed a more reliable method of cystine supersaturation measurement that may greatly aid in the diagnosis and especially the management of cystinuria (Nakagawa et al, 2000).

Patients with cystinuria may demonstrate additional metabolic anomalies on 24-hour urine studies (Sakhaee et al, 1989). In controlled dietary assessment of 27 patients with cystinuria, hypercalciuria was noted in 18.5% of patients and hyperuricosuria in 22.2%. Hypocitraturia was identified in 44.4% and was associated with

defective renal acidification in 80% of the patients in whom it was tested. The authors noted that hypercalciuria, hyperuricosuria, and hypocitraturia frequently accompany cystinuria and speculated that these conditions might be renal in origin, rather than a result of dietary or environmental aberrations. They further concluded that these unrelated anomalies may contribute to the formation of calcium and uric acid stones, which sometimes complicate cystine nephrolithiasis.

KEY POINTS: CYSTINURIA

- Cystinuria manifests when concentrations exceed 250 mg/L.
- Cystinuria may be accompanied by other metabolic abnormalities.
- Cystine stone formation is based solely on urinary cystine concentration.

Infection Calculi (Struvite)

Struvite calculi form in the presence of alkaline urine ($\text{pH} > 7.2$) and in an environment rich in ammonia (Nemoy and Staney, 1971). The ammonia is thought to be produced by the splitting of urea by colonization with bacteria that produce urease. The details of this process are presented in Chapter 51. Many bacterial organisms are able to produce this enzyme (Table 52-6), the most notorious of which is *Proteus mirabilis*. Although *Escherichia coli* is not able to split urea, it may be associated with struvite calculi in up to 13% of infections (perhaps through a metachronous infection).

Patients with these calculi may present with the symptoms of acute pyelonephritis, including fevers, chills, flank pain, dysuria, frequency, urgency, and malodorous, cloudy urine. Some patients may exhibit more chronic symptoms of malaise, fatigue, loss of appetite, and generalized weakness. Rarely, infections and obstruction have been long-standing enough to produce xanthogranulomatous pyelonephritis, which may cause the failure of an entire kidney or may just affect a portion. Spontaneous fistulae may develop to external surfaces or to peritoneal contents (Fig. 52-8).

Women are more often affected with struvite calculi than men, likely because of an increased susceptibility to urinary tract colonization. A history of a foreign body (e.g., forgotten stent, suture material, staple) or neurogenic bladder may be noted. Struvite calculi can be quite large and often fill multiple calyces or even the entire collecting system (Fig. 52-9). Urine cultures often will reveal a bacterial pathogen, although, as noted previously, the presence of a sterile urine culture does not preclude the sequestration of bacteria within the calculus itself.

There is debate concerning the incidence of associated metabolic anomalies in patients with struvite calculi. Resnick (1981) advocates the performance of a metabolic evaluation for all patients with infection calculi, because of a high incidence of positive findings. Conversely, Lingeman and colleagues (1995) studied 22 patients with infection calculi and noted that patients with pure struvite calculi were significantly less likely to have metabolic anomalies on 24-hour urine evaluation than those patients with mixed compositions of struvite and calcium oxalate. More recently, Iqbal and colleagues (2013) reviewed their experience with struvite stones. They reported that 60% of pure struvite-stone formers and 77% of mixed struvite-stone formers had metabolic abnormalities on 24-hour urine collections. The most common abnormalities were hypercalciuria and hypocitraturia.

KEY POINTS: INFECTION CALCULI (STRUVITE)

- Women produce more infection calculi than men.
- The urine pH is usually greater than 6.5 to 7.0.
- Urea-splitting organisms are frequent.
- Infection calculi commonly produce staghorn stones.

Figure 52-7. Cystine calculi are radiopaque on plain film, but are less dense than other calcium-based calculi. **A,** Note the stone (arrows) within the lower pole of this duplicated system. **B,** Similar to uric acid stones, the cystine calculus (arrows) is more clearly distinguished during the excretory phase of the intravenous pyelogram.

TABLE 52-6 Urea-Splitting Organisms

ORGANISMS	USUALLY (>90% OF ISOLATES)	OCCASIONALLY (5%-30% OF ISOLATES)
Gram positive	<i>Proteus rettgeri</i> <i>Proteus vulgaris</i> <i>Proteus mirabilis</i> <i>Proteus morganii</i> <i>Providencia stuartii</i> <i>Haemophilus influenzae</i> <i>Bordetella pertussis</i> <i>Bacteroides corrodens</i> <i>Yersinia enterocolitica</i> <i>Brucella</i> spp.	<i>Klebsiella pneumoniae</i> <i>Klebsiella oxytoca</i> <i>Serratia marcescens</i> <i>Haemophilus parainfluenzae</i> <i>Bordetella bronchiseptica</i> <i>Aeromonas hydrophila</i> <i>Pseudomonas aeruginosa</i> <i>Pasteurella</i> spp.

Figure 52-8. A, Computed tomography image of a staghorn calculus within the right kidney. Arrow points to a fistula that spontaneously eroded through the triangle of Petit. This patient denied a history of recurrent urinary tract infections. B, Nuclear renogram of the same patient as in A. Note the complete lack of function of the affected kidney. This organ was removed laparoscopically.

Figure 52-9. Plain film of a patient with bilateral staghorn calculi composed entirely of struvite. This patient had a history of recurrent urinary tract infections dating back 15 years.

Low Urine Volumes (<2000 mL)

Some patients will exhibit very few abnormalities other than low urine volumes on a complete evaluation. From a simplistic view, a low volume of urine output will concentrate the molecular components of crystal formation and raise the supersaturation risk. Intuitively, a patient with a relative state of dehydration will trend toward acidic urine, lowering the urine pH toward the pKa of uric acid (5.5) and potentially consuming titratable buffers such as citrate.

Many patients with low urine volumes work in professions that induce high insensible losses of fluid (e.g., manual labor, outdoor exposure) (Sakhaee et al, 1987; Borghi et al, 1990, 1993a). Many

BOX 52-5 Potential Causes of Erroneous 24-Hour Urine Collection Results

- Error in collection technique (e.g., improper use of preservatives, ice)
- Failure to collect a full 24 hours' worth of urine
- Changes in the patient's diet for the sake of the study
- Intermittent indiscretions in diet
- Failure of specimen to accurately represent typical day
- Bacterial contamination

work in environs that do not allow easy access to fluids and work breaks (assembly line, surgeons). A focused social history should elucidate these factors and allow for proper identification and subsequent counseling.

No Disturbances

Pak and associates (1980a) estimated that 3% of all patients undergoing a full metabolic evaluation will demonstrate no abnormalities. Although on the surface, these patients may present less of a diagnostic challenge, there is always a concern that the collections are not representative of the patient's true metabolic state (Box 52-5). This could be secondary to an error in collection technique, failure to collect a full 24 hours' worth of urine, changes in the patient's diet for the sake of the study, or intermittent indiscretions in diet. Furthermore, it is important to remember that a 24-hour urine collection represents a pooled sample. Heavy oxalate loading at one particular meal or bolus replacement of fluids at the end of a work day may produce average values that look normal, but actually hide periods of extreme urine parameters that promote stone formation. Finally, most patients will collect their requested 24-hour specimens on days when they are home and able to stay close to the collection container. For most, this occurs on a weekend or nonworking day. It is very possible (and quite likely)

TABLE 52-7 Diagnostic Criteria

	SERUM			URINARY							
	Ca	P	PTH	Ca FASTING	Ca LOAD	Ca RESTRICTED	UA	Ox	Cit	pH	Mg
Absorptive hypercalciuria type I	N	N	N	N	↑	↑	N	N	N	N	N

Infection lithiasis	N	N	N	N	N	N	N	N	↓	↑	N

Fasting samples represent 2-hour collections obtained in morning after an overnight fast. Calcium load samples were obtained over a 4-hour period subsequent to oral ingestion of 1 g calcium.

↑, high; ↓, low; Cit, citrate; Mg, magnesium; N, normal; Ox, oxalate; PTH, immunoreactive parathyroid hormone; UA, uric acid.

that collections on these days do not represent the patient's typical metabolic milieu that exists during the rest of the week (Rodgers et al, 1994, 1995; Norman, 1996; Hess et al, 1997).

The diagnostic criteria for the 12 principal classifications described in this section are summarized in Table 52-7.

CONSERVATIVE MEDICAL MANAGEMENT

Certain conservative recommendations should be made for all patients regardless of the underlying cause of their stone disease. Unfortunately, it can be difficult to reach consensus regarding specific details from the available literature.

Fluid Recommendations

Volume

One mainstay of conservative management is the forced increase in fluid intake to achieve a daily urine output of at least 2 liters (Borghi et al, 1999). Increased urine output may have two effects. First, the mechanical diuresis that ensues may prevent urinary stagnation and the formation of symptomatic calculi. It is more likely that the creation of dilute urine alters the supersaturation of stone components. Indeed, Pak and colleagues (1980b) measured in vitro and in vivo effects of urinary dilution and discovered that both significantly reduced the urinary activity product ratio (state of saturation) of calcium phosphate, calcium oxalate, and monosodium urate. Moreover, the formation product ratio—that is, the minimum supersaturation needed to elicit spontaneous nucleation—of calcium oxalate significantly increased.

Researchers at the University of Chicago demonstrated that failure to increase urine output was one of three very strong predictors of relapse for patients followed in a dedicated stone clinic (Strauss et al, 1982a). The previously described stone clinic effect has been primarily attributed to increases in fluid intake and attendant increases in urinary output (Hosking et al, 1983).

However, although the concept of increased fluid intake is quite simple, it can be quite difficult to achieve patient compliance. Anecdotally, most physicians with an interest in kidney stone disease have seen that many patients are unable to maintain increased urinary output over the long term. This general impression has been borne out in an analysis of urine output changes from a large series

of 2877 patients (Parks et al, 2003a). In this amalgam of university and private practice patients, the average increase in urinary volume was only 0.3 L/day. In addition, intermittent compliance may not be effective, because small, early stones may develop during periods of intense dehydration. At least one author suggested that if a patient is able to voluntarily force fluid intake long enough to dilute renal concentrating abilities, then thirst mechanisms will take over and help maintain a high fluid intake and high urine output (Burns and Finlayson, 1981). Unfortunately, the more recent data from Parks and colleagues (2003a) has not proved this finding to be reliable.

Water Hardness

If water intake is so important, is there a difference between levels of water hardness that might ameliorate or augment its benefit? This concept has been the topic of conflicting articles within the general urologic and epidemiologic literature. In one study, patients with a known history of calcium nephrolithiasis were divided according to postal zip codes. Twenty-four-hour urine measurements were compared, as was the history of stone episodes (Schwartz et al, 2002). Although the 24-hour urine calcium, magnesium, and citrate levels increased directly with drinking water hardness, no significant change was found in urinary oxalate, uric acid, pH, or volume. Most importantly, the number of total lifetime stone episodes was similar between patients residing in areas with soft public water and hard public water. Patients consuming the softest water formed 3.4 lifetime stones, and those who consumed the hardest water developed 3.0 lifetime stones. The authors noted that although water hardness can alter urinary parameters, this factor ultimately appears to have little effect on clinical outcome.

These findings are further supported by earlier work from Shuster and associates (1982). They examined 2295 patients from two regions: the Carolinas, which had soft water and high stone incidence, and the Rockies, which had hard water and low stone incidence. Home tap water samples from urinary stone patient hospitalizations were compared with controls. After adjusting for environmental factors, no significant difference between the two groups was obtained in tap water calcium, magnesium, and sodium concentrations. An incidental but potentially important finding was that those consuming water from a private well had an estimated relative risk for stone formation of 1.5 compared to those using public water. They ultimately concluded that water hardness should be a minor concern with respect to stone formation.

Unfortunately, this issue has not been completely put to rest, because there is still evidence that hard water may confer some excess risk for stone formation. In a well-controlled study involving fixed diets and a crossover design, 18 subjects with a history of calcium nephrolithiasis drank only hard water, soft water, or tap water (Bellizzi et al, 1999). The urinary levels of calcium demonstrated a significant 50% increase in the absence of changes of oxalate excretion. Although these changes are concerning, it is important to note that stone events were not used as a primary outcome. Another recent controlled diet study also demonstrated an increase in urinary calcium-to-creatinine ratio in stone formers who consumed hard water versus water that was less hard (Mirzazadeh et al, 2012).

Carbonated Beverages

A number of studies suggest that carbonated water offers increased protection against recurrent stone formation as compared to still water (Rodgers 1997, 1998; Bren et al, 1998; Caudarella et al, 1998; Coen et al, 2001). It should be noted that these studies focused primarily on carbonated water, which has been demonstrated to increase urinary citrate levels.

Other types of carbonated beverages have been examined. One study demonstrated that increased intake of soda can confer an increased risk for subsequent stone recurrence (Shuster et al, 1992). The study sample consisted of 1009 male subjects, who reported consuming at least 160 mL/day of soft drinks. Half of the subjects were randomized to refrain from consuming soft drinks, and the remaining subjects served as controls. The intervention group had an observed 6.4% advantage in actuarial 3-year freedom from recurrence over the control group. One important secondary finding was that those who reported that their most consumed drink was acidified by phosphoric acid but not citric acid had a 15% higher 3-year recurrence-free rate than the controls. Meanwhile, those who consumed drinks acidified by citric acid had no increase in stone episodes when compared to controls. A number of citrus-flavored sodas (orange flavored, lemon/lime flavored) have been shown to have high citrate content, which may aid in stone prevention (Haleblian et al, 2008; Eisner et al, 2010a).

Recently, a comparison of self-selected diets to standardized diets combined with regulated fluid intake with still water, or two sugar-free, caffeine-free carbonated beverages (one with high citrate content) documented no difference in urinary parameters among the standardized diets with regulated fluid intake, but a significant increase in urinary volume and a decrease in calcium oxalate saturation when these were compared to the self-selected diets (Passman et al, 2009).

Additional epidemiologic studies have demonstrated the effects of particular fluids on the risk for stone recurrence (Curhan et al, 1996a, 1998b). For both men and women, there was a decrease in the risk for nephrolithiasis for those who consumed increased volumes of water, caffeinated or decaffeinated coffee, tea, beer, and wine. Conversely, daily servings of apple or grapefruit juice increased the risk for stone events. Despite the epidemiologic evidence, the supersaturation risks associated with grapefruit juice have largely been discredited by subsequent evaluations (Goldfarb and Asplin, 2001; Trinchieri et al, 2002; Honow et al, 2003).

In contrast to these epidemiologic findings, recent evidence suggests that caffeine intake may increase the risk for stone recurrence in calcium-stone formers by increasing the excretion of calcium. Caffeine increased urinary calcium/creatinine, magnesium/creatinine, citrate/creatinine, and sodium/creatinine, but not oxalate/creatinine in stone formers and controls. Furthermore, supersaturation calculations increased, despite the noted increases in the inhibitors citrate and magnesium (Massey and Sutton, 2004).

Citrus Juices

Lemonade and orange juice have long been used as an adjunct to water to provide increased urinary volume as well as increased urinary citrate excretion. In a study of 12 hypocitraturic patients,

lemonade made from reconstituted lemon juice provided enough citrate to correct the hypocitraturia in 7 subjects (Seltzer et al, 1996). Urinary calcium excretion decreased an average of 39 mg daily, whereas oxalate excretion was unchanged. The lemonade mixture was well tolerated, with only two patients reporting mild indigestion that did not require cessation of therapy. Wabner and Pak (1993) similarly evaluated the effects of orange juice on the urinary parameters of normal subjects and found that compared to potassium citrate, orange juice delivered an equivalent alkali load and caused a similar increase in urinary pH (6.48 vs. 6.75 from 5.71) and urinary citrate (952 vs. 944 from 571 mg/day). Therefore orange juice, like potassium citrate, decreased urinary undissociated uric acid levels and increased the inhibitor activity (formation product) of brushite (calcium phosphate). However, orange juice increased urinary oxalate and did not alter calcium excretion, whereas potassium citrate decreased urinary calcium without altering urinary oxalate. They concluded that orange juice could be beneficial in the control of calcareous and uric acid nephrolithiasis. Further work evaluating the effects of distilled water, orange juice, and lemonade are provided by Odvina (2006). In a randomized, crossover study under controlled metabolic conditions, 13 patients were evaluated. The author found that orange juice intake, and not lemonade or water, led to a higher urinary pH and increased urinary citrate level. Urinary calcium was not different between the groups but oxalate was elevated in the orange juice arm. Finally, the supersaturation of calcium oxalate and undissociated uric acid were lowest during the orange juice phase, but the brushite supersaturation was significantly higher during this phase.

In comparison, a recent evaluation of reconstituted lemonade (1 oz RealLemon in $\frac{3}{4}$ cup of water) compared to 60 mEq of potassium citrate did not identify an increase in the urinary citrate excretion for the lemonade arm (Koff et al, 2007). Additionally, patients on lemonade therapy did not significantly alter their urinary pH, but a slight, though nonsignificant, increase in urinary volume was noted. However, 48% of the patients in this study did not demonstrate hypocitraturia before treatment, potentially confounding the results.

Using nuclear magnetic resonance spectroscopy, the citrate concentrations of a number of commercially available citrus and citrus-based beverages was assessed (Haleblian et al, 2008). This finding confirmed that natural juices are highest in citrate and potassium content, with grapefruit juice containing the greatest amount of citrate (197.5 mEq/L), followed closely by lemon and orange juice (145.48 and 144.57 mEq/L, respectively). Of the commercially available citrus-based beverages, Crystal Light (Kraft Foods, Northfield, IL) exhibited the highest concentration of citrate (117.2 mEq/L). The clinical effects of citrus-based beverages in patients with hypocitraturia have yet to be studied but may offer alternatives to patients who are not agreeable to citrus juices.

Overall, most evidence suggests that it is not the type of fluid ingested that is important for stone prevention but rather the absolute amount of fluid volume taken in per day. We therefore encourage all of our stone formers to drink at least 3000 mL/day to maintain a urine output greater than 2500 mL/day.

KEY POINTS: FLUID RECOMMENDATIONS

- Patients should be strongly encouraged to consume enough fluids to produce 2 L/day.
- Water hardness is unlikely to play a significant role in recurrence risk.
- Carbonated water may confer some protective benefit.
- Soda flavored with phosphoric acid may increase stone risk, whereas those with citric acid may decrease risk.
- Citrus juices (particularly lemon and orange juices) may be a useful adjunct to stone prevention.

Dietary Recommendations

Although metabolic abnormalities probably contribute to the majority of risk factors for recurrent nephrolithiasis, increasing evidence suggests that dietary changes are having an important impact on renal stone disease. Indeed, recent studies have documented an increasing incidence of nephrolithiasis, along with a greater propensity of female stone disease, than previously reported. A more complete discussion of these trends can be found in the previous chapter on the epidemiology and pathophysiology of nephrolithiasis (Pak et al, 1997; Ramello et al, 2000; Trinchieri et al, 2000; Coward et al, 2003; Hesse et al, 2003; Stamatelou et al, 2003; Amato et al, 2004). Therefore alterations in diet and physical activity may significantly reduce the incidence of recurrent nephrolithiasis.

Protein Restriction

Epidemiologic studies from a number of countries have shown that the incidence of renal stones is higher in populations in which there is an increased animal protein intake. For example, in the northern and western regions of India, animal protein intake is approximately 100% greater than in the southern and eastern regions and the rate of kidney stones is four times greater. In the United Kingdom, the frequency of upper tract stone disease correlates with the per capita expenditure on foodstuffs (Robertson et al, 1979, 1982). This effect may be partly because protein intake is higher in affluent people, and stone formation, for some reason, seems to be higher in the economically advantaged. When populations are matched for economic status, the intake of protein and other dietary constituents does not differ in patients with recurrent stones and controls. Even in subjects thus matched, however, patients with stones secrete greater quantities of calcium in the urine than do controls for a given intake of protein (Wasserstein et al, 1987). Thus patients with stones may be more sensitive to dietary protein loading than normal subjects.

Protein intake increases urinary calcium, oxalate, and uric acid excretion and the mathematically calculated probability of stone formation even in normal subjects. Indeed, according to Burns and Finlayson (1981), ingestion of protein is second only to ingestion of vitamin D in enhancing intestinal absorption of calcium. Early investigations of purine loading in controlled clinical laboratory settings confirmed the risk for hypercalciuria and hyperuricosuria with a diet high in animal protein (Pak et al, 1978; Fellstrom et al, 1983; Breslau et al, 1988). Patients with stones also exhibit inappropriate hypercalciuria in response to carbohydrate, sodium, and oxalate intake. In one acute study, dietary protein restriction resulted in a decrease in calcium, phosphate, and oxalate (Liatsikos and Barbalias, 1999). In another study in hypercalciuric patients, protein restriction resulted in decreased urinary uric acid and increased urinary citrate as well (Giannini et al, 1999).

Borghesi and colleagues (2002) provide further support to the importance of dietary protein in stone formation. In a prospective fashion, patients were randomized to either a low-protein, low-salt, moderate-calcium diet or to a low-calcium diet. Although acknowledging that it is difficult to separate the potential effects of the three facets of the first diet, there was a convincing 50% reduction in stone events compared to those patients on the low-calcium diet (Borghesi et al, 2002). In another dietary study, the same group of investigators suggests that diets high in fruits and vegetables impart a significantly reduced risk for stone formation than do those diets high in animal protein (Meschi et al, 2004). Twelve normal subjects had fruits and vegetables eliminated from their diets, and 26 hypocitraturic calcium-stone formers (with low fruit and vegetable intake) had their diet supplemented with low-oxalate-containing fruits and vegetables. The normal subjects (without fruit and vegetable intake) demonstrated significant decreases in urinary potassium (−62%), magnesium (−26%), citrate (−44%), and oxalate (−31%) while increasing their urinary excretion of calcium (+49%) and ammonium (+12%). In contrast, the hypocitraturic calcium-stone formers (with increased fruit and vegetable intake) significantly increased

their urinary volume (+64%), pH (5.84 → 6.19), potassium (+68%), magnesium (+23%), and citrate (+68%) while decreasing excretion of ammonium (−18%). Finally, the relative supersaturation of calcium oxalate and calcium phosphate rose significantly for the normal subjects without fruit and vegetable intake while the supersaturation of calcium oxalate and uric acid fell in the stone formers with fruit and vegetable intake.

More recently, the Dietary Approaches to Stop Hypertension (DASH) style diet has been evaluated for its effect on kidney stone formation. The DASH diet is rich in fruit and vegetables, moderate in low-fat dairy products, and low in animal protein. In a prospective population-based study, higher DASH scores were associated with a lower risk for kidney stone formation (Taylor et al, 2009). The inhibitory effect of the DASH diet is likely related to increase in urinary citrate and urine volume. A higher DASH score was associated with a higher urinary citrate and an increased volume on 24-hour urine collection (Taylor et al, 2010).

Not all investigators have noticed the relationship between intake of meat and hypercalciuria. Brockis and colleagues (1982) demonstrated that mean urinary excretion of calcium and oxalate were similar in matched groups of vegetarians and nonvegetarians. A large study at the University of Pennsylvania found that patients with recurrent nephrolithiasis consumed a diet similar in composition to that of case controls (Goldfarb, 1994). Most studies, however, suggest that an increased intake of meat may exacerbate calcium oxalate stone disease.

Sodium Restriction

Sodium restriction has been widely recommended as an important element of dietary prevention of recurrent nephrolithiasis (Massey and Whiting, 1995). Indeed, the evidence implicating excess sodium ingestion as a cause of calcium stone disease comes from several authors in different countries. Ito and colleagues (1993) from Japan have noticed that calcium-stone formers had increased levels of sodium ingestion compared to the daily recommended allowances for the Japanese nation. They also found that stone formers consumed larger amounts of animal protein. They did not comment on whether the increased sodium ingestion was caused by the protein excess or whether it acted as an independent risk factor.

Researchers in Dallas, Texas have confirmed the effects of salt-loading in a controlled crossover study involving normal volunteers. In their study, 14 normal subjects participated in two phases of study of 10 days' duration each, comprising a low-sodium phase (basal metabolic diet containing 50 mmol/day of sodium) and a high-sodium phase (basal diet plus 250 mmol/day of sodium chloride). The high sodium intake significantly increased urinary sodium (34 to 267 mmol/day), calcium (2.73 to 3.93 mmol/day), and pH (5.79 to 6.15) and significantly decreased urinary citrate (3.14 to 2.52 mmol/day). They noted that a high sodium intake not only increased calcium excretion but also increased urinary pH and decreased citrate excretion. The net effect of a high-sodium diet was an increased propensity for the crystallization of calcium salts in urine (Sakhaee et al, 1993).

Additionally, the previously quoted investigation by Borghesi involving dietary manipulation included a low-salt diet, limited to 50 mmol/day of sodium chloride (Borghesi et al, 2002). When combined with animal protein restriction and moderate calcium ingestion, a reduced-sodium diet will decrease stone episodes by roughly 50%. Further work from Italy has demonstrated that calcium-stone formers who ingest large quantities of daily salt are more likely to suffer from decreased bone mineral density (Martini et al, 2000). In this study of 85 patients, all females were premenopausal, underscoring the risks for further osteopenia that they might develop later in life. After adjustment for calcium and protein intakes, age, weight, body mass index (BMI), urinary calcium, citrate and uric acid excretion, and duration of stone disease, multiple-regression analysis showed that a high sodium chloride intake (≥ 16 g/day) was the single variable that was predictive of risk for low bone density in calcium stone-forming patients (OR = 3.8).

Conversely, patients with hypocitraturic calcium oxalate stone formation may benefit from sodium supplementation (Stoller et al, 2009). Eight patients with isolated hypocitraturia, based on 24-hour urinalysis were managed with regular diet and potassium citrate for 7 days, followed by the addition of 3 g of daily sodium supplementation for 7 days. The cohort had significant increases in total urinary volume and sodium excretion over 24 hours but did not demonstrate significant increases in calcium, oxalate, and uric acid, which led to significant decreases in the urinary supersaturation relative risk ratio for calcium oxalate stones.

KEY POINTS: DIETARY RECOMMENDATIONS

- Randomized studies have confirmed the advantage of a diet with reduced animal protein (meat) intake.
- A diet high in fruits and vegetables imparts a reduced risk for stone formation over diets high in animal protein.
- Randomized trials have demonstrated a benefit of dietary sodium restriction in both normal volunteers and stone formers.

Obesity

Obesity has been associated with impaired carbohydrate tolerance and an inappropriate calcium response to glucose ingestion. Thus the hypercalciuria seen in meat eaters may be a function of increased body weight (Menon and Krishnan, 1983). Trinchieri and colleagues (1998b) found that daily urinary oxalate excretion was related to BMI in a group of stone formers. The association between body size and risk for stone formation was studied formally by the Curhan group (Curhan et al, 1998a). In two large cohorts—the Health Professionals Follow-Up Study (HPFS) and the Nurses Health Study (NHS)—the prevalence of stone disease history and the incidence of new stone formation were directly associated with weight and BMI. The magnitude of the association was greater in women than in men. Subsequently, Taylor and Curhan (2006) performed a subset analysis on the HPFS and NHS cohorts with evaluation of 24-hour urinalyses. Higher BMI was found to be associated with increased urinary excretion of oxalate, sodium, uric acid, calcium, and phosphorus, as well as lower pH. It is noted, however, that calcium excretion was no longer associated with BMI once corrected for phosphorus and sodium excretion, thereby suggesting calcium excretion is more closely related to composition of diet and not obesity.

These same cohorts of patients have been continuously followed, and the group from Boston has provided a recent update on the role of obesity and nephrolithiasis. **They demonstrated that increased BMI, larger waist size, and weight gain correlated with an increased risk for stone episodes. This increased stone risk was still more pronounced for women than men (Taylor et al, 2005).**

In a review of a large national database, Powell and colleagues (2000) examined the serum and 24-hour urine parameters from nearly 6000 patients with a history of nephrolithiasis. Within this cohort, obese patients had increased urinary excretion of sodium, calcium, magnesium, citrate, sulfate, phosphate, oxalate, uric acid, and cystine combined with a decrease in urinary pH. Furthermore, obesity was associated with increased urinary volumes and urine osmolality compared with the nonobese patients. Sodium and sulfate excretion is related to daily intake of salt and protein; thus these findings support the theory that excessive food consumption is linked to risk for nephrolithiasis in obesity. Despite the global changes in urinary metabolites, only obese women (compared to nonobese women) had an increase in the stone episodes. Similar findings from Siener and associates (2004) support the association of obesity with the risk for stone formation. In an analysis of urine chemistries from 527 calcium oxalate–stone formers, the authors identified positive correlations between BMI and sodium, phosphorus, and uric acid excretion and negative correlations between BMI

and urinary pH. Citrate and urinary volume did not correlate with BMI, unlike in Powell's report.

One component of the American diet that appears to be related to obesity and metabolic syndrome is fructose. Fructose adds a caloric load to the American diet and may additionally directly affect the risk for stone formation. Taylor and Curhan's (2008b) analysis of the HPFS and NHS (I and II) documented that increasing fructose intake correlated with an increasing relative risk for incident stone formation, regardless of BMI, caloric intake, or other risk factors. This simple sugar has been shown to increase urinary calcium excretion in both rats and humans in limited studies, as well as the production and excretion of uric acid in humans (Koh et al, 1989; Milne and Nielsen 2000; Taylor and Curhan, 2008b). A more recent study evaluating the impact of fructose consumption on stone risk found that there was no change in 24-hour urine calcium, oxalate, or uric acid excretion with increasing fructose consumption (Knight et al, 2010).

One study has specifically evaluated the metabolic disturbances of obese patients, defined as a BMI greater than 30 (Ekeruo et al, 2004). It was determined that the most common manifesting metabolic abnormalities among obese patients included gouty diathesis (54%), hypocitraturia (54%), and hyperuricosuria (43%), which manifested at levels that were significantly higher than those found in nonobese stone formers. When present, chemical stone analysis showed a predominance of uric acid calculi, implicating excessively acid urine in these subjects. Directed medical therapy and dietary recommendations were able to dramatically reduce stone episodes for these patients.

Metabolic Syndrome

Metabolic syndrome consists of a cluster of disease states—glucose intolerance, elevated blood pressure, dyslipidemia, and central obesity—that increase the risk for developing type 2 diabetes and coronary vascular disease. All of these issues are frequently found in the obese population. Assessment of the overall rise of type 2 diabetes, obesity, metabolic syndrome, and stone disease suggests potential correlation among these states. A number of investigations have shown an increased risk for stone disease in patients with metabolic syndrome (Kadlec et al, 2012; Sakhaee et al, 2012; Cho et al, 2013). Cho and colleagues (2013) reported on the stone composition of patients with metabolic syndrome. Although the most common stone composition was calcium oxalate, these patients had a significantly higher risk for having a uric acid stone compared to patients without metabolic syndrome.

A number of studies have identified an increased risk for stone disease in diabetics (Pak et al, 2003c; Taylor et al, 2005; Lieske et al, 2006; Weinberg et al, 2014). Lieske and colleagues (2006) identified an OR of 1.22 for diabetes among stone formers, whereas Taylor and associates (2005) found a relative risk of 1.31 to 1.38 of stone formation in patients with diabetes, depending on age and sex. These studies confirm the earlier work by Pak and coworkers, in which uric acid stones were identified in a statistically significant predominance for patients with diabetes, indicating innate metabolic abnormalities specific to patients with diabetes.

Recent studies suggest that the increased incidence of uric acid stone formation in obese stone formers may be secondary to the production of more acidic urine than in nonobese patients. Combined data from the two largest stone centers in the United States found that urine pH appears to be directly correlated with body size (Maalouf et al, 2004). Furthermore, patients with type 2 diabetes have been found to have lower urinary pH than nondiabetics independent of the formation of uric acid stones (Cameron et al, 2006). When evaluating patients who form uric acid stones, Sakhaee and associates (2002) identified a much higher incidence of diabetes (both types 1 and 2) compared to other groups. Because individuals with diabetes have impaired ammonium excretion, they have been shown to have an increased incidence of uric acid stone formation (Pak et al, 2003c; Abate et al, 2004). Finally, low urine pH has been shown to directly correlate with the number of metabolic syndrome features (Maalouf et al, 2007). From evaluation of

24-hour urinalyses in 148 non-stone forming patients, a statistically significant linear relationship was identified in which each additional characteristic of metabolic syndrome portended a decrease in urine pH. Additionally, the degree of insulin resistance was also inversely related to urinary pH.

Impact of Weight-Loss Diets

As the epidemic of obesity has increased in Western society, so too has the popularity of weight-reducing diets. Current dietary fads include the use of low-carbohydrate, high-protein, high-fat diets (Atkin's Diet, South Beach Diet, and Sugar Busters Diet). A number of studies have documented an increase in the urinary calcium load from increased protein intake (Licata et al, 1979; Breslau et al, 1988). In a study of the impact of a high-protein, low-carbohydrate diet (Atkins Diet), 10 healthy subjects engaged in a low-carbohydrate, high-protein diet for 6 weeks under the care of a clinical dietitian (Reddy et al, 2002). After 6 weeks, urine pH decreased from 6.09 to 5.67, net acid excretion increased by 51 mEq/day, urinary citrate levels decreased from 763 mg/day to 449 mg/day. In addition, urinary saturation of undissociated uric acid increased more than two-fold, urinary calcium levels increased from 160 mg/day to 248 mg/day, causing an estimated calcium balance decrease of 90 mg/day. **Therefore the consumption of a low-carbohydrate, high-protein diet delivers a marked acid load to the kidney, increases the risk for stone formation, and may increase the risk for bone loss.** Although changes in urinary parameters are recognized, there has yet to be a study investigating the incidence of stone disease in a population conforming to this diet. Potentially, addition of alkali therapy may reduce the acidosis and hypercalciuria, while normalizing citrate metabolism without increase in caloric intake. **As mentioned earlier, a diet high in fruits and vegetables and low in animal protein, specifically the DASH diet, is associated with a reduced risk for stone formation (Taylor et al, 2009).**

Impact of Bariatric Surgery

Bariatric surgery continues to increase in popularity and administration as rates of obesity rise. Historically, the initial weight-loss operation was jejunioileal bypass. As a result of the significant complications associated with this procedure—liver disease, malnutrition, bone disease, arthritis, kidney failure, and renal calculi—the Food and Drug Administration banned its application in 1979 (Clayman et al, 1978).

In 2005 the most common bariatric procedure was Roux-en-Y gastric bypass (RYGB), accounting for 70% to 90% of weight-loss surgeries in the United States (Santry et al, 2005). A worldwide survey study performed in 2011 demonstrated that RYGB made up 46.6% of weight-loss procedures, followed by sleeve gastrectomy (27.8%) and adjustable gastric banding (17.8%) (Buchwald and Oien, 2013). Though initially thought to have a significantly lower risk for stone disease, a number of studies have reported a risk for oxalate nephropathy and nephrolithiasis in the RYGB population (Nelson et al, 2005; Asplin and Coe, 2007; Nasr et al, 2008). Nelson and associates (2005) identified 14 of 23 patients presenting with an incident stone event at a mean of 29 months. More sobering is that 2 patients in this study and 11 patients in a report from the Columbia group developed oxalate nephropathy and progressed to end-stage renal disease requiring dialysis. Twenty-four-hour urinary assessment in stone formers after RYGB identified an elevated mean oxalate excretion (83 mg/day vs. 34 mg/day, $P < .001$) compared to normal non-stone formers. These studies evaluated patients with nephrolithiasis after RYGB; therefore the incidence of new-onset stone formation and prevalence of hyperoxaluria in this population cannot be determined.

Prospective data are emerging that evaluate this population before and after bariatric surgery (Sinha et al, 2007; Duffey et al, 2008). Urinary oxalate excretion was noted to increase significantly in both investigations, but with varying time courses. Duffey and associates (2008) found an increase from 31 mg/day to 41 mg/day ($P < .05$) at 3 months after surgery; Sinha and colleagues (2007)

identified a significant increase in urinary oxalate excretion at 12 months postoperatively. In an attempt to quantify the prevalence of hyperoxaluria, a multi-institutional study evaluated 58 non-stone forming patients 6 months after bariatric surgery (RYGB and biliopancreatic diversion) (Patel et al, 2009). The authors found a 74% and 26% prevalence of hyperoxaluria (>45 mg/day) and profound hyperoxaluria (>100 mg/day), respectively, on a single 24-hour urine collection, which decreased to 52% and 9%, respectively, when two 24-hour urinalyses were evaluated.

Adjustable gastric banding has been gaining in popularity as a means of weight-loss surgery. Penniston and colleagues (2009b) evaluated 24-hour urine collections after bariatric surgery in 27 patients who underwent RYGB and 12 patients who underwent gastric banding. The patients who underwent RYGB were found to have low urine volumes, hypocitraturia, and hyperoxaluria. However, the patients who underwent adjustable gastric banding were found only to have low urine volume, suggesting they may not be at as high a risk for stone formation. Another study comparing 24-hour urine parameters in patients who underwent RYGB, adjustable gastric banding, and sleeve gastrectomy found significantly lower 24-hour urine oxalate in those who underwent either adjustable gastric banding or sleeve gastrectomy compared to RYGB (Semins et al, 2010). In a retrospective review of patients who underwent either adjustable gastric banding or sleeve gastrectomy, Chen and colleagues (2013) found a very low incidence of kidney stones in either cohort. These studies suggest that restrictive bariatric surgery incurs a lower risk for subsequent stone development than RYGB.

Currently, the pathophysiology of bariatric surgery-induced hyperoxaluria remains unclear. Potential causes include alteration in intestinal flora (i.e., *Oxalobacter formigenes*), fat malabsorption, or a reduced amount of oxalate secretion. However, as the rate of bariatric surgery increases lockstep with the rising tide of obesity, identification of the mechanisms and treatment strategies will become increasingly important to minimize the risk for increased stone formation.

KEY POINTS: OBESITY

- Obesity is an independent risk factor for nephrolithiasis, particularly for women.
- Metabolic syndrome is associated with lower urinary pH.
- Obese patients have a higher propensity for uric acid calculi.
- High-protein, low-carbohydrate diets alter urinary parameters and may increase the risk for stone formation.
- Roux-en-Y-gastric bypass surgery may significantly increase the overall risk for stone formation.

Role of Dietary Calcium

The preponderance of evidence now supports the maintenance of a moderate calcium intake in the face of calcareous nephrolithiasis (Curhan et al, 1993; Curhan, 1997; Takei et al, 1998; Trinchieri et al, 1998a; Martini and Wood, 2000; Lewandowski et al, 2001; Borghi et al, 2002; Heller et al, 2003; Taylor et al, 2004). Older recommendations to significantly restrict calcium intake likely led to an increase in available intestinal oxalate. As a result, this limitation in dietary calcium may subsequently increase oxalate absorption, thereby raising the supersaturation of calcium oxalate. As noted earlier, a prospective, randomized study has shown that patients on a moderate-calcium diet, combined with salt restriction and moderation of animal protein had half as many stone episodes as those who attempted to follow a calcium-restricted diet (Borghi et al, 2002). Review of a large cohort of middle-aged nurses revealed that there was a decreased incidence of nephrolithiasis in subjects who had increased levels of dietary calcium (Curhan, 1997; Curhan et al, 1997). Interestingly, this protection did not remain for those who received increased calcium intake from supplements instead of from dietary sources (i.e., dairy products).

There is further evidence to suggest that calcium supplementation can be safe if attention is paid to preparation and especially to timing. In a review of postmenopausal women, authors have demonstrated that initiation of calcium supplementation does not have deleterious effects on urinary calcium, oxalate, or citrate levels. Furthermore, calcium supplement with a meal or combined calcium supplement and estrogen therapy was not associated with a significant increased risk for calcium oxalate stone formation in the majority of postmenopausal osteoporotic patients (Domrongkitchaiporn et al, 2002b). Additional work from the same group determined that the timing of calcium supplementation may have positive or negative effects (Domrongkitchaiporn et al, 2004). In a study of healthy male recruits, the authors compared the urinary effects of calcium carbonate supplementation taken with meals versus at bedtime. In both instances, urinary calcium excretion increased equal amounts. However, for those taking the calcium supplement with meals, this increase was offset by an equally significant decrease in urinary oxalate. As a result, there was no increase in urinary supersaturation of calcium oxalate when calcium supplementation was taken with meals, a protection that did not remain for the nighttime bolus ingestion.

Evidence also suggests that the type of calcium supplementation may have an impact on the potential of stone formation. Two long-term studies from researchers in Dallas document that supplementation with calcium citrate does not have a significant impact on stone formation. Calcium citrate is an over-the-counter calcium preparation that provides 950 mg of calcium citrate and 200 mg of elemental calcium in each tablet. As with other available calcium supplements, calcium citrate will significantly increase urinary calcium excretion. Yet, this preparation offers the benefit of also increasing urinary citrate excretion. The concomitant increase in citruria potentially offsets the lithogenic potential of calcium supplement-induced hypercalciuria and therefore provides a more stone-friendly calcium supplement (Sakhaee et al, 2004).

One clinical trial further studied the effects of long-term calcium citrate supplementation in premenopausal women. This investigation demonstrated that the urinary saturation of calcium oxalate and calcium phosphate (brushite) did not significantly change during calcium citrate therapy. It appears that the lack of calcium supplement-induced hypercalciuria was secondary to the down-regulation of intestinal calcium absorption, because of prolonged calcium supplementation and the inhibitory effects of citrate included in the calcium citrate preparation. The results of this long-term calcium citrate trial suggest that calcium supplementation using calcium citrate does not increase the propensity for crystallization of calcium salts within the urine. This protective effect is most likely due to an attenuated increase in urinary calcium excretion (from a decrease in fractional intestinal calcium absorption), a decrease in urinary phosphorus, and an increased citruric response (Sakhaee et al, 1994).

Role of Vitamin D and Bisphosphonates

Controversy exists over the role of vitamin D supplementation and kidney stone formation. The Women's Health Initiative randomized clinical trial comparing calcium plus vitamin D supplementation versus placebo in postmenopausal women found a 17% increased incidence of self-reported stones in the group receiving calcium plus vitamin D. The increased risk was not associated with any other demographic factors (Wallace et al, 2011). In this study, vitamin D was used as a supplement and not for repletion of low vitamin D levels.

Two studies have evaluated the effects of vitamin D repletion on 24-hour urine calcium. Leaf and associates (2012) enrolled 29 calcium-stone formers with low serum vitamin D. Participants were given vitamin D 50,000 international units once per week for 8 weeks. The mean serum vitamin D levels increased significantly during the study from 17 ± 6 ng/mL to 35 ± 10 ng/mL; however, the mean 24-hour urine calcium did not increase (257 ± 54 mg/day to 255 ± 88 mg/day) (Leaf et al, 2012). Despite the fact that there was no overall change in urinary calcium for the entire

cohort, 11 of the participants did have an increase in their 24-hour urine calcium. The authors recommend monitoring of 24-hour urine calcium in patients who undergo vitamin D repletion. Penniston and colleagues (2009a) evaluated 24-hour urine calcium excretion in postmenopausal women with no history of stones undergoing vitamin D repletion. They also found no overall difference in calcium excretion.

Bisphosphonates are common treatment for osteoporosis. A recent prospective study compared the effects of alendronate alone to alendronate combined with hydrochlorothiazide in patients with calcium stones, hypercalciuria, and decreased bone density. Both groups showed a significant decrease in urinary calcium and increase in bone density. The combination of alendronate and hydrochlorothiazide had a significantly greater effect on urinary calcium and bone density than alendronate alone (Arrabal-Polo et al, 2013). It appears that bisphosphonates are safe and possibly preventive for patients with calcium nephrolithiasis.

KEY POINTS: ROLE OF DIETARY CALCIUM, VITAMIN D, AND BISPHOSPHONATES

- Dietary calcium restriction actually increases stone recurrence risk.
- Calcium supplementation is likely safest when taken with meals.
- Calcium citrate appears to be a more stone-friendly calcium supplement because of the additional inhibitory action of citrate.
- Vitamin D repletion is likely safe for stone formers; however, 24-hour urine calcium should be monitored during vitamin D therapy.
- Bisphosphonates combined with thiazide diuretics appear to reduce hypercalciuria while protecting the bone.

Oxalate Avoidance

The contribution of dietary oxalate consumption to urinary oxalate can vary. Some have estimated that only 10% to 20% of urinary oxalate is usually derived from dietary sources (Williams and Wandzilak, 1989). More recently, Holmes and associates (2001) found that the contribution of dietary oxalate to urinary oxalate ranged from $24.4\% \pm 1.5\%$ on a diet of 10 mg/day of oxalate to $41.5\% \pm 9.1\%$ on a diet of 250 mg/day of oxalate. They also demonstrated that the mean contribution of dietary oxalate increased when calcium consumption decreased (Holmes et al, 2001). Although dietary oxalate clearly plays a role in increased urinary oxalate, it is difficult to restrict its intake because oxalate is ubiquitous and found in most vegetable matter. However, it is important to avoid large portions of foodstuffs that are rich in oxalate, such as spinach, beets, chocolate, nuts, and tea. Whereas general advice on a restricted-oxalate intake might be given to patients with recurrent nephrolithiasis, a low-oxalate diet would be most useful in patients with enteric hyperoxaluria, those with underlying bowel abnormalities, or patients who have undergone gastric bypass surgery (Holmes and Assimos, 2004). Box 52-3 presents an extensive list of foods containing a high level of oxalate. It is notable that recent work has illustrated similar relationships of dietary intake and urinary excretion of oxalate in a cross-sectional analysis of HPFS and NHS (I and II) for both stone formers and non-stone formers, thereby further adding to the question of the impact that dietary oxalate has on urinary oxalate excretion (Taylor and Curhan, 2008a).

Repeated concerns have been raised regarding the risk of vitamin C (ascorbic acid) ingestion and the possibility of its conversion to oxalate with subsequent urinary excretion. Unfortunately, conflicting evidence has been presented by multiple authors (Weaver, 1983; Trinchieri et al, 1991, 1998b; Urivetzky et al, 1992; Curhan et al, 1996b, 1999; Baxmann et al, 2003; Traxer et al, 2003). In fact, conflicting conclusions have been reported even from the same

TABLE 52-8 Physicochemical and Physiologic Effects of Pharmacologic Therapy

Brushite saturation	Moderate decrease	Mild increase	Mild decrease	No change	No change

group of authors, underscoring the need for close scrutiny of presented data. Some of the confusion stems from differences in study end points. Although ingestion of large amounts of vitamin C may demonstrate increases in 24-hour oxalate excretion and therefore calcium oxalate supersaturation, this does not guarantee an eventual increase in the formation of symptomatic calculi. A recent large, prospective cohort of men found that increased ascorbic acid intake was associated with two-fold increased risk for kidney stone formation (Thomas et al, 2013).

In the end, it seems reasonable to avoid heavy dosing of vitamin C. Limiting one's intake to a maximum daily dose of less than 2 g is an easy recommendation to follow (Traxer et al, 2003).

KEY POINTS: OXALATE AVOIDANCE

- Avoidance of excess dietary oxalate loading is reasonable and intuitive.
- Vitamin C in large doses may increase the risk for stone recurrence. Doses should probably be limited to 2 g/day.

Conservative Management Summary

It is anticipated that with these conservative measures alone, a significant number of patients may be able to normalize their urinary risk factors for stone formation. Thus only these conservative measures may be necessary to keep their stone disease under control. After 3 to 4 months on conservative management, patients should be re-evaluated using either standard laboratory assays or an automated urinalysis package. If the patient's metabolic or environmental abnormalities have been corrected, the conservative therapy can be continued and the patient followed every 6 to 12 months with repeat 24-hour urine testing as indicated. It is believed that follow-up is essential not only to monitor the efficiency of treatment but also to encourage patient compliance. If, however, a metabolic defect persists, a more selective medical therapy may be instituted. For example, if significant hyperuricosuria (urinary uric acid > 800 mg/day) persists even after dietary restriction of meat products, medical therapy with allopurinol may be instituted.

SELECTIVE MEDICAL THERAPY OF NEPHROLITHIASIS

Improved elucidation of the pathophysiology and the formulation of diagnostic criteria for different causes of nephrolithiasis have made feasible the adoption of selective treatment programs (Pak et al, 1981; Preminger and Pak, 1985). Such programs should (1) reverse the underlying physicochemical and physiologic derangements, (2) inhibit new stone formation, (3) overcome nonrenal complications of the disease process, and (4) be free of serious side effects. The rationale for the selection of certain treatments is the

TABLE 52-9 Dosages of Common Medications Used to Prevent Urinary Calculi

MEDICATION	DOSAGE
Thiazide diuretics	
Hydrochlorothiazide	25 mg PO bid
Chlorthalidone	25-50 mg PO daily
Indapamide	2.5 mg PO daily
Sodium cellulose phosphate	10-15 g/day divided with meals
Orthophosphate	0.5 g PO tid
Potassium citrate	20 mEq PO bid-tid
Allopurinol	300 mg PO daily
Magnesium gluconate	0.5-1 g tid
Pyridoxine (B ₆)	100 mg PO daily
D-Penicillamine	250 mg PO daily (titrated to effect)
α-Mercaptopropionyl glycine	100 mg PO bid (titrated to effect)
Captopril	25 mg PO tid
Acetohydroxamic acid	250 mg PO bid-tid

assumption that the particular physicochemical and physiologic aberrations identified with the given disorder are etiologically important in the formation of renal stones (as previously discussed) and that the correction of these disturbances would prevent stone formation. Moreover, it is assumed that such a selective treatment program would be more effective and safe than "random" therapy. Despite a lack of conclusive experimental verification, these hypotheses appear reasonable and logical. Common medications used to treat urinary stone disease and their expected actions are summarized in Table 52-8. Medication dosages are noted in Table 52-9, and side effects are outlined in Table 52-10. A simplified treatment algorithm outlining basic evaluation and management is illustrated in Figure 52-10.

Efficacy Outside of an Academic Center

One potential criticism of the "selective" metabolic management of nephrolithiasis is that the collection of multiple urine and serum studies can be too time-consuming to be feasible outside of an academic medical center with its dedicated research staff. Although a commitment to follow-up can be tedious, it should be no worse for patients with kidney stones than it is for those followed for urologic cancer or voiding dysfunction.

Indeed, Lingeman and colleagues (1998) compared the results of patient management from seven private practices to that achieved by a dedicated university clinic. Of note, the specialized stone

TABLE 52-10 Potential Side Effects of Medications Used to Prevent Urinary Lithiasis

MEDICATION	SIDE EFFECT
Thiazide diuretics Hydrochlorothiazide Chlorthalidone Indapamide	Potassium wasting, muscle cramps, hyperuricosuria, intracellular acidosis, hypocitraturia
Sodium cellulose phosphate (SCP)	GI distress, hypomagnesemia, hyperoxaluria, PTH stimulation
Orthophosphate	Similar to SCP, soft tissue calcification
Potassium citrate	GI upset, hyperkalemia
Allopurinol	Rash, myalgia
Magnesium gluconate pyridoxine (B ₆)	Diarrhea
D-Penicillamine	Nephrotic syndrome, dermatitis pancytopenia
α -Mercaptopropionyl glycine	Rash, asthenia, rheumatologic complaints, GI distress, mental status changes
Captopril	Rash, cough, hypotension
Acetohydroxamic acid	Thromboembolic phenomena, tremor, headache, palpitations, edema, GI distress, loss of taste, rash, alopecia, anemia, abdominal pain

GI, gastrointestinal; PTH, parathyroid hormone.

management software and laboratory resources of the university clinic supported the private centers. They found that supersaturation values were effectively reduced in the network and stone clinic and that the reduction was proportional to the initial supersaturation value and increase in urine volume. The stone clinic achieved a greater supersaturation reduction, higher fraction of patient follow-up, and greater increase in urine volume, but the treatment effects in the network were, nevertheless, substantial and significant.

This finding is supported by a further study demonstrating the efficacy of medical prophylaxis when administered in a private practice setting (Mardis et al, 2004). When compared to conservative measures of dietary recommendations and fluid management, active pharmacologic treatment achieved a significantly greater reduction in stone episodes. These findings prompted Mardis and coworkers (2004) to conclude that medications validated in trials and guided by metabolic evaluation lower stone recurrence when used in a private practice setting, as they do in clinical trials from academic medical centers.

Absorptive Hypercalciuria

Thiazides

Currently no treatment program is capable of correcting the basic abnormality of absorptive hypercalciuria I and thiazide diuretics are not considered a selective therapy for absorptive hypercalciuria, because they do not decrease intestinal calcium absorption in this condition (Pak, 1979). However, this class of medication has been widely used to treat absorptive hypercalciuria, because of its hypocalciuric action and the high cost and inconvenience of alternative therapy (sodium cellulose phosphate, which is no longer available in the United States). The use of thiazides was first described by Yendt and colleagues (1966) for the treatment of undifferentiated hypercalciuria.

Thiazides directly stimulate calcium resorption in the distal nephron while promoting excretion of sodium. Long-term thia-

zide therapy results in volume depletion, extracellular volume contraction, and proximal tubular resorption of sodium and calcium. Thiazides may increase urinary excretion of magnesium and zinc, but these responses are not consistent. Potassium losses from thiazide therapy can cause hypocitraturia, as a result of hypokalemia with intracellular acidosis.

Studies indicate that thiazide may have a limited long-term effectiveness in absorptive hypercalciuria type I (Zerwekh and Pak, 1980; Preminger and Pak, 1987). Despite an initial reduction in urinary excretion, the intestinal calcium absorption remains persistently elevated. These studies suggest that the retained calcium may be accreted in bone at least during the first few years of therapy. Bone density, determined in the distal third of the radius by photon absorptiometry, increases significantly during thiazide treatment in absorptive hypercalciuria, with an annual increment of 1.34%. With continued treatment, however, the rise in bone density stabilizes and the hypocalciuric effect of thiazide becomes attenuated. These results suggest that thiazide treatment may cause a low turnover state of bone that interferes with a continued calcium accretion in the skeleton. The "rejected" calcium would then be excreted in urine. In contrast, bone density is not significantly altered in renal hypercalciuria, in which thiazide has been shown to cause a decline in intestinal calcium absorption commensurate with a reduction in urinary calcium.

Further work on this topic has been reported (Pak et al, 2003a). In this study, 28 patients with absorptive hypercalciuria type 1 were managed with thiazide (20) or indapamide (8) and potassium citrate for 1 to 11 years while maintained on low-calcium oxalate diet. Serum and urinary chemistry studies and bone mineral density were measured at baseline and at the end of treatment. During treatment, urinary calcium significantly decreased but urinary oxalate did not change. Urinary pH and citrate significantly increased, and urinary saturation of calcium oxalate significantly decreased by 46%. Stone formation rate decreased significantly from 2.94 to 0.05 per year. Notably, L2 to L4 bone mineral density increased significantly by 5.7% compared to normal peak value and by 7.1% compared with normal age-matched and gender-matched values. The authors concluded that dietary moderation of calcium and oxalate, combined with thiazide and potassium citrate, satisfactorily controlled hypercalciuria, while preventing the complication of osteopenia commonly associated with absorptive hypercalciuria.

Although side effects are generally mild, they occur in approximately 30% to 35% of patients treated with thiazides. Side effects are usually seen on initiation of treatment but disappear with continued therapy. Lassitude and sleepiness are the most common symptoms and can occur in the absence of hypokalemia. Potassium supplementation always should be considered, particularly in patients with evident potassium deficiency, patients on digitalis therapy, and those individuals who develop hypocitraturia. Addition of potassium citrate has been documented to prevent occurrence of hypokalemia and hypochloremic metabolic acidosis in patients undergoing long-term thiazide therapy (Odvina et al, 2003). Thiazides also may cause impaired carbohydrate tolerance and hyperuricemia. A more distressing complication is decreased libido or sexual dysfunction, which is seen in a small percentage of patients. It is reasonable to check a basic metabolic panel 1 to 2 weeks after initiating thiazides to monitor for hypokalemia, particularly if the patient is not started on potassium citrate concurrently.

Occasionally, thiazides unmask primary hyperparathyroidism (i.e., "thiazide challenge"). Patients with normal serum calcium may develop elevated serum calcium on thiazides (Wermers et al, 2007). Wermers and colleagues (2007) reported this occurs an average of 6 years after initiation of thiazide. In this heterogeneous population (3% of which were known stone formers), hyperparathyroidism was diagnosed in 64% of patients who had persistently elevated serum calcium after the thiazide was stopped. Another way a thiazide challenge can be used is to differentiate primary and secondary hyperparathyroidism (Eisner et al, 2009). In patients with nephrolithiasis, hypercalciuria, and elevated serum parathyroid hormone, hydrochlorothiazide 25 mg orally twice daily was

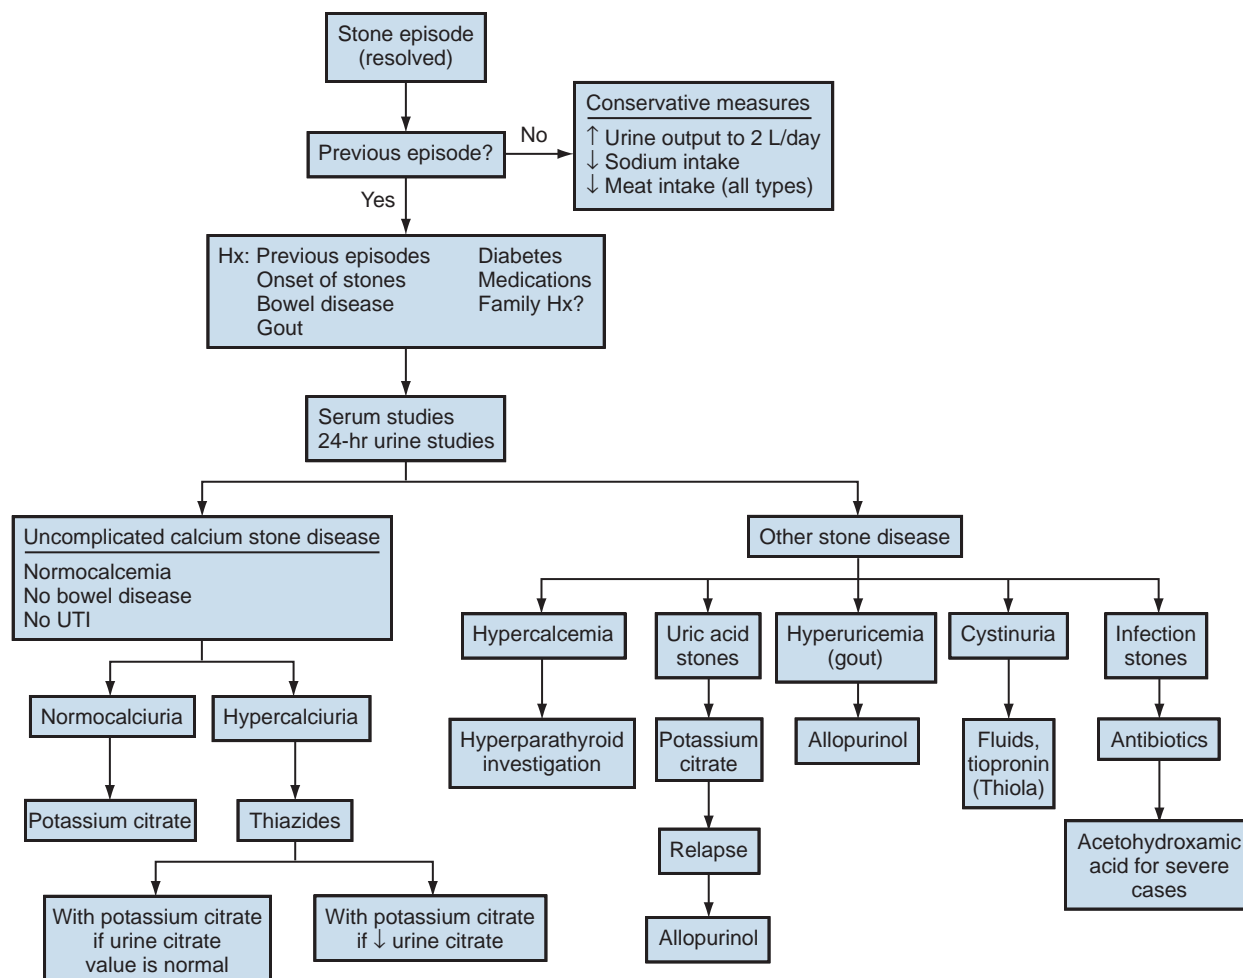

Figure 52-10. Simplified treatment algorithm for the evaluation and medical management of urinary lithiasis. Hx, history; UTI, urinary tract infection. (Modified from C. Y. Pak.)

administered for 2 weeks. If the parathyroid hormone remains elevated, the diagnosis of primary hyperparathyroidism is confirmed. If it returns to normal, the diagnosis is secondary hyperparathyroidism from renal leak hypercalciuria.

Sodium Cellulose Phosphate

Sodium cellulose phosphate, given orally, is a nonabsorbable ion exchange resin that binds calcium and inhibits calcium absorption (Pak et al, 1974). Unfortunately, despite early enthusiasm, the use of sodium cellulose phosphate has largely fallen out of favor and this medication is no longer available in the United States.

Guidelines for the Use of Thiazides in Absorptive Hypercalciuria

Thiazides do not correct the basic, underlying physiologic defect in absorptive hypercalciuria. Some guidelines are offered until more selective therapy can be developed.

In patients with absorptive hypercalciuria type I, thiazide is the first choice and should be combined with potassium citrate and dietary moderation of dairy products (2 or 3 servings per day) and restriction in dietary sodium and oxalate. If thiazides lose their hypocalciuric action (after long-term treatment), a drug holiday may be instituted and then thiazide therapy may be resumed. It is recommended that potassium citrate and dietary alterations continue during this period. Further research is warranted to identify a medication that will selectively reduce increased intestinal calcium absorption, thereby decreasing the calcium load available for urinary excretion and stone formation.

Other Hypocalciuric Agents

Other long-acting agents are preferred in place of hydrochlorothiazide for the treatment of hypercalciuria. These medications include chlorthalidone (25 to 50 mg/day) or indapamide (2.5 mg/day). Indapamide is technically not a thiazide but does share a successful hypocalciuric effect with the other agents. Both of these agents have been shown to be equally efficacious, yet may improve patient compliance with more convenient once-daily dosing (Jaeger et al, 1986; Lemieux, 1986; Coe et al, 1988; Ettinger et al, 1988; Ohkawa et al, 1992; Borghi et al, 1993b; Martins et al, 1996).

Amiloride in combination with thiazide (Moduretic) may be more effective than thiazide alone in reducing calcium excretion (Maschio et al, 1981; Leppla et al, 1983). However, this medication does not augment citrate excretion. Because amiloride is a potassium-sparing agent, potassium replacement is not necessary and could, in fact, be problematic. It is not advisable to provide potassium supplementation to patients receiving a potassium-sparing diuretic. Although the potassium-sparing effects of amiloride may be beneficial, the use of triamterene, another potassium-sparing agent, should be undertaken with caution because of reports of triamterene stone formation (Watson et al, 1981; Werness et al, 1982; Ettinger, 1985; Sorgel et al, 1985).

Absorptive Hypercalciuria Type II

In absorptive hypercalciuria II, no specific drug treatment may be necessary because the physiologic defect is not as severe as in absorptive hypercalciuria I. In addition, many patients show disdain for drinking fluids and therefore excrete concentrated urine. A moderate calcium intake (400 to 600 mg/day) and high fluid intake

(sufficient to achieve a minimum urine output > 2 L/day) would seem ideally indicated, because normocalciuria could be restored by dietary calcium restriction alone, and increased urine volume has been shown to reduce urinary saturation of calcium oxalate. Moreover, avoidance of excessive sodium intake might further decrease hypercalciuria and potential stone formation in patients with absorptive hypercalciuria II.

Orthophosphate

Orthophosphate (neutral or alkaline salt of sodium and/or potassium, 0.5 g phosphorus three or four times per day) has been shown to inhibit 1,25-(OH)₂D synthesis (Van Den Berg et al, 1980; Insogna et al, 1989). However, there is as yet no convincing evidence from randomized trials that this treatment restores normal intestinal calcium absorption. Orthophosphate reduces urinary calcium probably by directly impairing the renal tubular reabsorption of calcium and by binding calcium in the intestinal tract. Urinary phosphorus is markedly increased during therapy, a finding reflecting the absorbability of soluble phosphate. Physicochemically, orthophosphate reduces the urinary saturation of calcium oxalate but increases that of brushite. Moreover, the urinary inhibitor activity is increased, probably owing to the stimulated renal excretion of pyrophosphate and citrate. Although contrary reports have appeared, this treatment program has been reported to cause soft tissue calcification and parathyroid stimulation (Dudley and Blackburn, 1970). Orthophosphate is contraindicated in nephrolithiasis complicated by UTI because of the increased phosphorus load.

KEY POINTS: ABSORPTIVE HYPERCALCIURIA

- Sodium cellulose phosphate effectively decreases the absorption of intestinal calcium but has been abandoned because of GI intolerance and side effects.
- Thiazides do not treat the underlying cause of absorptive hypercalciuria, but do reduce urinary calcium and manage its symptoms.
- Care should be taken when using diuretics to prevent hypokalemia with subsequent hypocitraturia.
- Orthophosphates may have a role for the treatment of absorptive hypercalciuria when other methods are ineffective.

Renal Hypercalciuria

Thiazides are ideally indicated for the treatment of renal hypercalciuria. This diuretic has been shown to correct the renal leak of calcium by augmenting calcium reabsorption in the distal tubule and by causing extracellular volume depletion and stimulating proximal tubular reabsorption of calcium. The ensuing correction of secondary hyperparathyroidism restores normal serum 1,25-dihydroxyvitamin D (1,25-[OH]₂D) and intestinal calcium absorption. Thiazides have been shown to provide a sustained correction of hypercalciuria commensurate with a restoration of normal serum 1,25-(OH)₂D and intestinal calcium absorption for up to 10 years of therapy (Preminger and Pak, 1987).

Physicochemically, the urinary environment becomes less saturated with respect to calcium oxalate and brushite during thiazide treatment, largely because of the reduced calcium excretion. Moreover, urinary inhibitor activity, as reflected in the limit of metastability, is increased by an unknown mechanism. These effects are shared by hydrochlorothiazide 25 mg twice per day, chlorthalidone 25 to 50 mg/day, or indapamide 2.5 mg/day. Potassium citrate supplementation (40 to 60 mEq/day) is advised, because this medication has been shown to be effective in averting hypokalemia and increasing urinary citrate, when administered to patients with

calcium nephrolithiasis taking thiazide (Nicar et al, 1984; Pak et al, 1985a).

A more complete discussion of the mechanism of action, efficacy, and side effects of thiazides for the treatment of hypercalciuria is presented in the preceding section. Furthermore, Table 52-11 provides a summary of the results of randomized trials involving the use of thiazides for the treatment of hypercalciuria. Of note, a recent meta-analysis of medical therapies for calculus prevention demonstrated that only thiazides have shown strong evidence for efficacy in randomized trials (Pearle et al, 1999).

KEY POINT: RENAL HYPERCALCIURIA

- Thiazides are first-line therapy for the treatment of renal leak hypercalciuria.

Primary Hyperparathyroidism

Parathyroidectomy is the optimum treatment for nephrolithiasis in patients with primary hyperparathyroidism (Parks et al, 1980; Fraker, 2000). This therapy may include the resection of a dominant adenoma or a removal of all four hyperplastic glands. After removal of abnormal parathyroid tissue, urinary calcium is expected to return to normal, commensurate with a decline in serum calcium and intestinal calcium absorption. However, these findings are not always dependable, because some patients may suffer from changes in tubular and glomerular functions as a result of long-standing hypercalcemia/hypercalciuria (Farias et al, 1996). Moreover, it is imperative to repeat a 24-hour urinary calcium determination to make sure the hypercalciuria has resolved.

There is no established medical treatment for the nephrolithiasis of primary hyperparathyroidism. Although orthophosphates have been recommended for the disease of mild-to-moderate severity, their safety or efficacy has not yet been proved. These medications should be used only when parathyroid surgery cannot be undertaken. Estrogen has been reported to be useful in reducing serum and urinary calcium in postmenopausal women with primary hyperparathyroidism (Herbai and Ljunghall, 1983; Marcus et al, 1984; Coe et al, 1986; Selby and Peacock, 1986; Boucher et al, 1989; Diamond et al, 1996; Orr-Walker et al, 2000).

KEY POINT: PRIMARY HYPERPARATHYROIDISM

- Hyperparathyroidism complicated by stone disease is best treated with surgical excision of the adenoma(s).

Hyperuricosuric Calcium Oxalate Nephrolithiasis

There are two pharmacologic approaches to the management of hyperuricosuric calcium nephrolithiasis. The first involves decreasing the production of uric acid. Allopurinol (300 mg/day) may be used to block the ability of xanthine oxidase to convert xanthine to uric acid (Coe, 1978). The resultant decrease in serum uric acid will ultimately lead to a decrease in urinary uric acid as well. Allopurinol's use in hyperuricosuria associated with dietary purine overindulgence also may be reasonable if patients are unable or unwilling to comply with dietary purine restriction. Physicochemical changes ensuing from restoration of normal urinary uric acid include an increase in the urinary limit of metastability of calcium oxalate (Pak et al, 1978). Thus the spontaneous nucleation of calcium oxalate is slowed by allopurinol treatment, probably via inhibition of monosodium urate-induced stimulation of calcium oxalate crystallization (Pak et al, 1979; Coe et al, 1980). Because of the potential exaggeration of monosodium urate-induced calcium oxalate crystallization, a moderate sodium restriction (150 mEq/day) is also advisable.

TABLE 52-11 Randomized Trials Using Thiazides for the Management of Nephrolithiasis

YEAR	AUTHOR	DIAGNOSIS	AGENT	NO. PATIENTS	NO. CONTROLS	EFFICACY	FOLLOW-UP	COMMENTS
1981	Brocks et al	Recurrent calcium stones	Bendroflumethiazide, 2.5 mg tid	29	33	83% remission in controls, 85% in treated: not significant	1.6 yr	Not all patients were hypercalciuric. Only 16% of expected stones formed in controls, 24% in treated
1982	Scholz et al	Recurrent calcium stones	Hydrochlorothiazide, 25 mg bid	25	26	77% remission in controls, 76% in treated: not significant	1 yr	Fasting urinary calcium increased before treatment, decreased with thiazides, but not in controls. Urine output increased in both groups, indicating that hydration was sufficient
1984	Laerum and Larsen	Recurrent stone formers	Hydrochlorothiazide, 25 mg bid	25	25	45% remission in controls, 75% in treated: significant difference. Controls formed 21 stones, treated formed 230 stones: not significant	3 yr	General practice study. 75% of patients did not have hypercalciuria. Differences seen only after 18 mo
1988	Ettinger et al	Recurrent calcium stones	Chlorthalidone, 25 or 50 mg/day	42	31	55% remission in controls, 86% in treated: significant	3 yr	Only 15% of patients had hypercalciuria. Compliance to diet not encouraged or assessed; to drugs, assessed. Urine output not measured. 16% dropout rate in controls, 35%-40% dropout rate with chlorthalidone
1984	Wilson et al	Recurrent calcium stone	Hydrochlorothiazide, 100 mg/day	21	23	65% remission in controls, 70% in treated: not significant. 0.32 stone/yr in controls; 0.15 stone/yr in treated: significant	<3 yr	Not all patients had hypercalciuric stones. Other treatments—phosphates, magnesium, allopurinol—were ineffective
1992	Ohkawa et al	Idiopathic hypercalciuria	Trichlormethiazide, 4 mg/day	82	93	86% remission in controls, 92% in treated: not significant. Stone formation rate significantly lowered in treated patients	3 yr	This was a multi-institutional study. All patients had hypercalciuria. Many were single-stone formers
1993b	Borghi et al	Idiopathic hypercalciuria	Indapamide, 2.5 mg/day, or indapamide plus allopurinol, 300 mg/day	25	25	65% remission in controls, 95% in treated: significant		Urinary output did not rise in either group; thus hydration may not have been effective
TOTAL				249	256	73% remission in controls, 85% in treated patients		Beneficial effects with treatment seen only in trials with follow-up of ≥ 2 yr

There are few convincing randomized trials demonstrating the efficacy of allopurinol for the treatment of hyperuricosuria. However, one study by [Ettinger and colleagues \(1986\)](#) does stand out. In this double-blind, prospective, randomized trial, allopurinol was given to 60 patients with hyperuricosuria, normocalciuria, and recurrent calcium oxalate stones. A 6-month grace period was established, during which any new calculus that was passed was not considered to represent failure of therapy. With a follow-up of up to 39 months, new stone events (stone growth or recurrence) occurred in 58% of the patients on placebo and 31% of the patients on allopurinol. The placebo group had 63.4% fewer calculi, whereas the allopurinol group had 81.2% fewer calculi. The mean rate of calculus events was 0.26 per patient per year in the placebo group and 0.12 in the allopurinol group. The allopurinol group had a significantly longer time before the recurrence of stones.

Alternatively, management of hyperuricosuria may be approached by altering the urinary milieu such that uric acid remains in a dissolved state ([Pak and Peterson, 1986](#)). Central to this approach would be the obvious advantage of copious amounts of dilute urine to maintain uric acid at a low concentration. Attempts to maintain the urine at a pH above the pKa also may be successful by promoting dissolution of this molecule ([Pak et al, 1986b](#)). This effect is usually achieved by the use of an alkalinizing agent such as potassium citrate (at a dose of 30 to 60 mEq/day in divided doses). In the study by Pak and colleagues, the treatment produced a sustained rise in urinary pH by 0.55 to 0.85 to the high normal range. Urinary citrate levels rose by 249 to 402 mg/day. Commensurate with these changes, urinary saturation of calcium oxalate (relative saturation ratio) and the amount of undissociated uric acid declined significantly. Stone formation declined from 1.55 per patient-year to 0.38 per patient-year during the mean treatment period of 2.35 years. Stones ceased to form in 16 of 19 patients during treatment.

There is some evidence that changes in urinary pH alone are inadequate for the management of hyperuricosuria ([Pak et al, 2002b](#)). If this is the case, the efficacy of citrate for the management of hyperuricosuria calcium nephrolithiasis may stem from the inhibitory activity of citrate with respect to calcium and oxalate crystallization.

Potassium citrate may be particularly useful in patients with mild-to-moderate hyperuricosuria (<800 mg/day), especially in whom hypocitraturia is also present.

KEY POINTS: HYPERURICOSURIC CALCIUM OXALATE NEPHROLITHIASIS

- Patients with hyperuricosuria should be instructed to decrease dietary purine intake.
- Allopurinol can decrease uric acid production and may be ideal for those patients with a history of gout.
- Potassium citrate can effectively alter the urinary milieu in patients with hyperuricosuria by decreasing the supersaturation of uric acid and calcium oxalate.

Enteric Hyperoxaluria

The management of patients with enteric hyperoxaluria usually involves directed therapy that addresses several abnormalities or abnormal physiology. Oral administration of over-the-counter calcium preparations (0.25 to 1 g four times per day) or magnesium has been recommended for the control of calcium nephrolithiasis of ileal disease ([Worcester, 2002](#)). Although urinary oxalate may decrease (probably from binding of oxalate by divalent cations), the concurrent rise in urinary calcium may obviate the beneficial effect of this therapy, at least in some patients ([Barilla et al, 1978](#)).

Cholestyramine has also been suggested for the management of calculi in this disorder ([Stauffer, 1977](#)). This medication may be

useful by binding bile salts in the bowel lumen, thereby decreasing the irritation of the colonic mucosa and the subsequent hyperabsorption of oxalate ([Caspary et al, 1977](#)). The replacement of dietary fat with medium-chain triglycerides may be helpful in patients who also have malabsorption.

Patients may exhibit hypomagnesiuria as a result of impaired intestinal absorption of magnesium. Because magnesium has been shown to complex oxalate, hypomagnesiuria may increase the urinary saturation of calcium oxalate ([Caudarella et al, 1993](#)). Although oral magnesium supplements may correct hypomagnesiuria, they also may provoke further diarrhea. Magnesium gluconate (0.5 to 1 g three times per day) appears to be better tolerated than magnesium oxide or hydroxide. **Treatment with potassium citrate (60 to 120 mEq/day) may correct the hypokalemia and metabolic acidosis in patients with enteric hyperoxaluria and, in some individuals, increase urinary citrate toward normal.** Consideration should be given to providing the liquid form of potassium citrate in patients with rapid GI transit times, because the liquid form of this medication may be better absorbed than the slow-release, wax matrix pills.

A high fluid intake is recommended to ensure adequate urine volume. Excessive fluid loss may be present, and an antidiarrheal agent may be necessary before sufficient urine output can be achieved. Calcium citrate may theoretically have a role in management of enteric hyperoxaluria. This treatment may lower urinary oxalate by binding oxalate in the intestinal tract. Calcium citrate also may raise the urinary citrate and pH by providing an alkali load ([Harvey et al, 1985](#)). Finally, calcium citrate may correct the malabsorption of calcium and adverse effects on the skeleton by providing an efficiently absorbed formulation of calcium.

Recently, the use of probiotics and the alteration of gut flora have been investigated ([Hoppe et al, 2005](#); [Lieske et al, 2005](#)). The goal of these strategies is to increase the degradation of oxalate, thereby preventing intestinal absorption. The use of lactic acid bacteria and *O. formigenes* has preliminarily demonstrated reduction in urinary excretion of oxalate. Larger, long-term assessment is needed, but further investigation into this relatively novel treatment approach is clearly warranted.

Pyridoxine has been used to treat patients with elevated oxalate in primary hyperoxaluria. It is converted to pyridoxal phosphate, which is a cofactor for AGT. Deficiency of AGT is the cause of primary hyperoxaluria type 1. Pyridoxine has been shown to increase the expression, catalytic activity, and peroxisomal import of AGT ([Fargue et al, 2013](#)). It also has been reported for patients with idiopathic hyperoxaluria. In a retrospective study, [Ortiz-Alvarado and colleagues \(2011\)](#) found that a combination of dietary counseling (low-oxalate diet) and pyridoxine significantly reduced urinary oxalate in patients with idiopathic hyperoxaluria. The authors did not note any side effects from pyridoxine treatment. This may be an alternative treatment for patients with refractory hyperoxaluria.

KEY POINTS: ENTERIC HYPEROXALURIA

- Fluid intake should be strongly encouraged to correct the relative state of dehydration.
- Dietary calcium may help bind intestinal oxalate and decrease its absorption.
- Slow-release formulations of citrate should be avoided.

Hypocitraturic Calcium Oxalate Nephrolithiasis

In patients with hypocitraturic calcium oxalate nephrolithiasis, potassium citrate treatment is capable of restoring normal urinary citrate, lowering the urinary saturation, and inhibiting crystallization of calcium salts. Because hypocitraturia is found in a number of different conditions, each will be addressed individually.

Distal Renal Tubular Acidosis

Potassium citrate therapy is able to correct the metabolic acidosis and hypokalemia found in patients with distal RTA (Preminger et al, 1985; Wang and Preminger, 2011). In addition, this medication is capable of restoring normal urinary citrate, although large doses (up to 120 mEq/day) may be required in severe acidotic states. With correction of the acidosis, urinary calcium should decline into the normal range. Because urinary pH is generally high to begin with in patients with RTA, the overall rise in urinary pH is small.

Potassium citrate therapy typically produces a sustained decline in the urinary saturation of calcium oxalate (from reduction in urinary calcium and in citrate complexation of calcium). The urinary saturation of calcium phosphate does not increase because the rise in phosphate dissociation is relatively small and is adequately compensated by a decline in ionic calcium concentration. In addition, the inhibitory activity against the crystallization of calcium oxalate and calcium phosphate is augmented because of the direct action of citrate.

Investigators from Thailand suggest that the target dose of potassium citrate for children with distal RTA should be 3 to 4 mEq/kg per day in divided doses (Domrongkitchaiporn et al, 2002c; Tapaneay-Olarn et al, 2002).

Chronic Diarrheal States

The full management of enteric stone disease has been discussed previously in this chapter. Part of the entire management should involve the use of citrate to correct the acidosis that accompanies the chronic bicarbonate losses with diarrhea. The amount of potassium citrate will depend on the severity of hypocitraturia in these patients, with dosages ranging from 60 to 120 mEq in three or four divided doses.

It is recommended that a liquid preparation of potassium citrate be used rather than the slow-release tablet preparation; the slow-release medication may be poorly absorbed because of rapid intestinal transit time. In addition, frequent dose schedules (3 or 4 times per day) for the liquid preparation is necessary because this form of the medication has a relatively short duration of biologic action.

Thiazide-Induced Hypocitraturia

As noted previously, thiazide therapy may cause hypocitraturia as a result of thiazide-induced hypokalemia with resultant intracellular acidosis (Nícar et al, 1984). Therefore it should be a common practice to administer potassium supplementation, preferably in the form of potassium citrate, to patients receiving thiazides for treatment of hypercalciuria. Potassium citrate has been shown to be equally effective as potassium chloride in correcting thiazide-induced hypokalemia. Moreover, the addition of potassium citrate not only prevents a fall in urinary citrate during thiazide therapy, but may raise citrate excretion (Pak et al, 1985b).

Idiopathic Hypocitraturic Calcium Oxalate Nephrolithiasis

This entity includes hypocitraturia occurring alone, as well as in conjunction with other abnormalities (e.g., hypercalciuria or hyperuricosuria). Stones formed in this condition are predominantly composed of calcium oxalate. Potassium citrate therapy may produce a sustained increase in urinary citrate and a decline in the urinary saturation of calcium oxalate (Pak and Fuller, 1986). Two agents have been used for the treatment of hypocitraturia: sodium potassium citrate, commonly used in Europe, and potassium citrate—in liquid form or as a wax matrix tablet—used in the United States. The usual therapeutic dose is 30 to 60 mEq/day given in divided doses or as a single evening dose (Berg et al, 1992). Sodium citrate does not lower urinary calcium excretion, perhaps as a result of the increased sodium load associated with this therapy (Sakhaee et al, 1983; Preminger et al, 1988).

In general, citrate is well tolerated, although the potential for gastric upset is real. The current formulation of potassium citrate embedded within a wax matrix may help alleviate the risk for gastric irritation. Patients are strongly encouraged to take this medication with meals to act as a further buffer.

Long-term therapy with this medication has been shown to provide a favorable durable response in alteration of urinary parameters and stone formation rate (Robinson et al, 2009). In a retrospective cohort of 503 patients on potassium citrate therapy for a mean of 41 months (range 6 to 168), urinary pH and citrate demonstrated significant increases (pH, 5.9 to 6.46; citrate, 470 to 700 mg/day), with substantial improvement in urinary parameters in as little as 6 months of therapy. In addition potassium citrate decreased the stone formation rate from 1.89 stones per patient per year to 0.46.

Concern has been raised, however, regarding the overalkalinization of urine and an increase in the formation rate of calcium phosphate stones. Researchers analyzed a large stone database of over 1200 patients and identified a three-fold increase in calcium phosphate content of stones over the last three decades (Parks et al, 2004). As would be expected, rising urinary pH was directly associated with this finding, therefore raising the question of the role of potassium citrate in this finding of increasing calcium phosphate content. The same group of researchers then analyzed patients who transformed their stone content to increased calcium phosphate and found that those patients who transformed did receive more potassium citrate compared to those who did not transform (Parks et al, 2009). The authors point out that the effect on urinary pH is possibly offset by the rise in urinary citrate.

Further work on this issue has shown that although the urinary pH does increase while patients are taking long-term potassium citrate, the stone formation rate in patients with a urine pH greater than 6.5 is as significantly decreased as in patients with a potassium citrate-treated pH less than 6.5. Although stone composition was not evaluated in this particular study, the lack of difference in the stone formation rate in patients with a high urine pH strongly suggests that citrate administration does not increase the risk for calcium phosphate stone formation (Robinson et al, 2009).

KEY POINTS: HYPOCITRATURIC CALCIUM OXALATE NEPHROLITHIASIS

- Citrates are generally well tolerated, with only a small risk for GI upset.
- Citrates are first-line therapy for the management of RTA, thiazide-induced hypocitraturia, and idiopathic hypocitraturia.
- There is conflicting evidence of an increased risk of calcium phosphate stone formation with the long-term use of potassium citrate therapy.

Hypomagnesuric Calcium Nephrolithiasis

Hypomagnesuric calcium nephrolithiasis is characterized by low urinary magnesium, hypocitraturia, and low urine volume. Therefore management should include restoration of urinary magnesium levels with either magnesium oxide or magnesium hydroxide, as well as correction of the hypocitraturia with potassium citrate. The administration of magnesium salts was first advocated on the theory that it reduced urinary excretion of oxalate. Some magnesium salts increase urinary magnesium excretion and thus produce a more favorable magnesium-to-calcium ratio in the urine, a condition that offers relative protection against stone formation. Magnesium decreases renal tubular citrate resorption through the chelation of citrate and thus increases urinary citrate excretion. Melnick and coworkers (1971) found that stone recurrence dropped from 6 stones per year to 0.073 stone per year in a group of 149 recurrent calcium oxalate-stone formers treated with magnesium oxide. Prien and Gershoff (1974) reported that

approximately 70% of patients administered 300 mg of magnesium oxide and 100 mg of pyridoxine demonstrated complete cessation of stone formation. [Johansson and associates \(1980\)](#) treated 56 patients with 400 to 500 mg of magnesium hydroxide. Of the treated patients, 80% were free of stones, in comparison to 50% who did not receive magnesium supplementation. The rate of stone formation dropped from 0.8 stone per year to 0.03 stone per year in the treated patients and from 0.5 stone per year to 0.22 stone per year in the control subjects. At least one randomized trial showed no difference in recurrence rates between treated and untreated patients ([Ettinger et al, 1988](#)).

Several magnesium salts have been used for the treatment of stone disease. Magnesium oxide and magnesium hydroxide are poorly absorbed and produce only a slight decrease in urinary oxalate and a modest increase in urinary magnesium ([Barilla et al, 1978](#); [Johansson et al, 1980](#)). Urinary calcium levels are increased during magnesium oxide supplementation ([Melnick et al, 1971](#); [Fetner et al, 1978](#); [Tiselius et al, 1980](#)), and thus urinary saturation of calcium oxalate is not significantly lowered with magnesium oxide. [Lindberg and colleagues \(1990\)](#) found that either magnesium citrate or magnesium oxide induced only modest beneficial changes in urinary biochemistry when administered on an empty stomach. When the magnesium salts were provided with meals, however, they caused more prominent changes in urinary biochemistry and lowered the relative saturation of urine with calcium oxalate or brushite.

GI intolerance is the major side effect of magnesium therapy. At this time, magnesium supplementation is not widely used. Magnesium supplementation had been used in patients with sodium cellulose phosphate for the treatment of patients with absorptive hypercalciuria type I and currently may be used with potassium citrate in patients with chronic diarrheal syndromes.

A new magnesium preparation (potassium-magnesium citrate) has been developed, but not yet approved for use, that provides both magnesium and citrate in the same tablet. This formulation of potassium-magnesium citrate has been shown to provide as much bioavailable potassium as other preparations ([Koenig et al, 1991](#)). In addition, magnesium excretion was significantly increased, as was the excretion of urinary citrate. The ability to deliver potassium has been further studied as it relates to thiazide-induced hypokalemia. This medication was demonstrated to provide just as much bioavailable potassium as other, standard, agents ([Wuermser et al, 2000](#)).

[Ettinger and colleagues \(1997\)](#) reported on a randomized, double-blind trial of potassium-magnesium citrate versus placebo. In their study, new calculi formed in 63.6% of subjects receiving placebo and in 12.9% of subjects receiving potassium-magnesium citrate. When compared with placebo, the relative risk for treatment failure for potassium-magnesium citrate was 0.16. The authors concluded that potassium-magnesium citrate effectively prevents recurrent calcium oxalate stones and could be depended on to provide up to 85% protection over 3 years. Similar to work performed with potassium citrate, [Odvin and colleagues \(2006\)](#) demonstrated the ability of potassium-magnesium citrate in preventing hypokalemia and hypomagnesemia in patients on thiazide therapy.

KEY POINTS: HYPOMAGNESURIC CALCIUM NEPHROLITHIASIS

- Magnesium supplementation can provide benefits in stone reduction.
- The use of magnesium has been limited by the risk for diarrhea.
- Potassium-magnesium may restore urinary magnesium and citrate levels with minimal GI side effects.

Gouty Diathesis

The major goal in the management of gouty diathesis is to increase the urinary pH above pH 5.5, preferably between 6.0

and 6.5 ([Khatchadourian et al, 1995](#)). In the past, urine alkalinization has been accomplished with either sodium bicarbonate or various combinations of sodium and potassium alkali therapy. Although sodium alkali may enhance dissociation of uric acid and inhibit uric stone acid formation by raising urinary pH, this medication may be complicated by the development of calcium-containing stones (calcium phosphate and/or calcium oxalate). Potassium citrate is advantageous because it is not only a good alkalinizing agent, but it appears to be devoid of the complication of calcium stones. Potassium citrate should be given at doses sufficient to maintain urinary pH at approximately 6.5 (30 to 60 mEq/day in two or three divided doses). **Attempts at alkalinizing the urine to a pH of greater than 7.0 should be avoided. At a higher pH, there is a danger of increasing the risk for calcium phosphate stone formation.** If the urinary uric acid excretion is elevated or hyperuricemia exists, allopurinol (300 mg/day) should be added.

Cystinuria

The object of treatment for cystinuria is to reduce the urinary concentration of cystine to below its solubility limit (200 to 300 mg/L) ([Pak and Fuller, 1983](#)). The initial treatment program includes a high fluid intake to attempt to produce 2½ to 3 liters of urine per day. This amount of urine output will dramatically raise the denominator of the concentration fraction and help reduce the supersaturation of urine with respect to cystine. Others have recommended the oral administration of soluble alkali (potassium citrate) at a dose sufficient to raise the urinary pH to 6.5 to 7.0 ([Chow and Streem, 1998](#); [Joly et al, 1999](#)). This treatment strategy attempts to increase the solubility of the filtered cystine to prevent crystal formation. Although alkali therapy may help, it is important to remember that the pKa of cystine is 8.3, which creates two problems. First, it is quite difficult to achieve a urine pH this high, making excessive alkalinization an unrealistic target. Second, raising the urine pH to these levels will put the patient at risk for the formation of calcium phosphate calculi.

There is good evidence that excess dietary sodium can lead to increases in cystine excretion ([Norman and Manette 1990](#); [Lindell et al, 1995](#); [Rodriguez et al, 1995](#); [Fjellstedt et al, 2001](#)). Indeed, these authors have demonstrated that the restriction of dietary sodium should be an integral aspect of the global management of cystinuric patients. [Fjellstedt and colleagues \(2001\)](#) demonstrated that the use of sodium citrate rather than potassium citrate may diminish the efficacy of other medical interventions, such as the sulfhydryl-containing compound α -mercaptopyrionylglycine (Thiola).

When this conservative program is ineffective, the next line of therapy involves the use of agents that increase cystine solubility in urine by formation of a more soluble mixed-disulfide bond (i.e., cystine to drug, rather than cystine to cystine). These agents include α -mercaptopyrionylglycine (tiopronin [Thiola]), D-penicillamine (Cuprimine), and captopril.

The first agent studied was D-penicillamine. Interestingly, very little has been written specifically about this agent and its use in the treatment of cystinuria since the 1960s to 1970s ([Crawhall and Thompson, 1965](#); [McDonald and Henneman, 1965](#); [Lotz et al, 1966](#); [Combe et al, 1993](#)). Although moderately effective, D-penicillamine quickly became associated with frequent side effects, including nephrotic syndrome, dermatitis, and pancytopenia. One recent study documented 9 of 11 patients without toxicity for an average of 109 months of follow-up after an initial dose escalation ([DeBerardinis et al, 2008](#)). Typical doses start at 250 mg/day and are titrated to effect.

The next medication to be introduced for the treatment of cystinuria was α -mercaptopyrionylglycine (tiopronin [Thiola]) ([Remien et al, 1975](#); [Hautmann et al, 1977](#); [Johansen et al, 1980](#)). This agent also contains a sulfhydryl group that forms a disulfide bond with cystine. Although it has been shown to be slightly less effective at capturing cystine molecules in vivo ([Harbar et al, 1986](#)), α -mercaptopyrionylglycine is better tolerated than D-penicillamine and therefore enjoys clinical superiority ([Pak](#)

et al, 1986a). However, side effects are still possible with tiopronin. Indeed, Pak and colleagues (1986a) demonstrated that overall side effects to α -mercaptopropionylglycine were relatively common, and occurred in 64.7% without a history of D-penicillamine treatment, compared to 83.7% who suffered toxicity to D-penicillamine. Moreover, serious adverse reactions requiring cessation of therapy were less common with α -mercaptopropionylglycine. Among the patients who took both drugs, 30.6% had to stop taking α -mercaptopropionylglycine, whereas 69.4% could not tolerate D-penicillamine. Common side effects include asthenia, GI distress, rash, joint aches, and mental status changes. Dosages start at 100 mg, taken orally two times per day and are titrated to achieve urinary concentrations of cystine less than 250 mg/L urine. Pak has reported total daily doses as high as 1200 mg (Pak et al, 1986a).

As described earlier in this chapter, Coe and colleagues have presented an assessment of cystine prophylaxis based upon the supersaturation of cystine in the presence of thiol-based medications (Coe et al, 2001). In essence, this assay measures how much “room” there is in the patient’s urine for more cystine to be dissolved. Demonstration that the urine is not yet fully saturated implies a lower risk for spontaneous stone formation.

Finally, the angiotensin-converting enzyme inhibitor captopril has been used to treat cystinuria because of its available sulfhydryl group. Although this agent enjoyed early enthusiasm (Sloand and Izzo, 1987; Streem and Hall, 1989; Cohen et al, 1995), its popularity seems to have waned (Michelakakis et al, 1993). Side effects are less severe than the other agents and include fatigue, hypotension, and chronic cough. Yet, there have been no long-term clinical trials demonstrating the effectiveness of captopril in preventing recurrent cystine stone formation.

The medical management of cystinuria can be quite challenging. Although the array of medication choices is not particularly complicated, it is often difficult to achieve patient compliance (Barbey et al, 2000). Indeed, because of the genetic nature of the disease process, these patients frequently begin their stone formation at a young age, thereby exposing their kidneys to the risk for chronic stone passage and potential parenchymal loss (Lindell et al, 1997). Assimos and colleagues (2002) examined the clinical status of 40 cystinuric patients followed at two medical centers and compared their kidney health to that of 3964 calcium oxalate–stone formers enrolled in a database. The mean serum creatinine for stone-forming cystinuric patients was significantly higher than that of the calcium oxalate cohort. Male gender, increasing number of open surgical stone removal procedures, and nephrectomy were significant variables associated with an increased serum creatinine. An alarming number of cystinuric patients had undergone nephrectomy for any reason (14%) versus the patients in the calcium oxalate cohort (3%).

Unfortunately, despite the obvious consequences of poor medical compliance, a recent study suggests that few patients are able to achieve and maintain targeted goals of medical intervention (Pietrow et al, 2003). Of the 26 patients followed at a dedicated stone center, only 15% achieved and maintained therapeutic success, as defined by urine cystine concentration less than 300 mg/L. An additional 42% achieved therapeutic success but subsequently had failure at an average of 16 months (range 6 to 27). Of these patients, two thirds were able to regain therapeutic success at an average of 9.4 months (range 4 to 20). However, 19% never achieved therapeutic success and an additional 23% failed to present to follow-up appointments or provide subsequent 24-hour urine studies, despite their having been referred to a tertiary care center. It is very important to note that patient self-assessment of medical compliance was uniformly high regardless of physician perceptions or treatment results.

Infection Lithiasis

The preferred management of struvite calculi involves aggressive surgical approaches. The American Urological Association Nephrolithiasis Guidelines Committee has strongly recommended

KEY POINTS: CYSTINURIA

- The medical compliance of patients with cystinuria can be poor.
- Treatment consists of aggressive fluid intake, urinary alkalization, salt avoidance, and the use of a cystine-binding agent.
- α -Mercaptopropionylglycine (Thiola) is the most frequently used cystine-binding agent.

endoscopic-based therapy (i.e., percutaneous nephrolithotomy) as the first-line therapy for managing complex renal staghorn calculi (Preminger et al, 2005). This report noted that complete elimination of all infected stone material is essential for the prevention of recurrent struvite stone formation. A complete discussion of surgical therapy for large calculi is beyond the scope of this chapter and can be found elsewhere within this text.

The medical management of infection calculi centers on the prevention of recurrence, rather than medical dissolution. Thus long-standing effective control of infection with urea-splitting organisms should be achieved if at all possible with improved bladder health, adequate urinary drainage, and suppressive antibiotics (Hess, 1990; Bichler et al, 2002). Unfortunately, such control is difficult to obtain in the face of residual calculi because stones often harbor organisms and endotoxin within their interstices (Rocha and Santos, 1969; McAleer et al, 2002, 2003). Antibiotics should be tailored to the predominant organism found on culture and sensitivity screening (Hugosson et al, 1990). Notably, cultures do not always correlate well between a patient’s urine and a resuspension of stone material (Fowler, 1984). Therefore strong clinical suspicion is always indicated, and all patients undergoing removal of presumed struvite calculi should be covered with broad-spectrum antibiotics that account for local resistance patterns. Although cultures may become negative during treatment, it is important to remember that recurrence of colonization is likely if residual fragments remain within the collecting system.

After surgical stone removal, residual fragments may be dissolved with hemiacidrin irrigation (Renacidin) under very careful observation. Historically, use of this agent was associated with significant toxicity and even death. Closer scrutiny revealed that many, if not most, of these cases involved the use of irrigation in infected urine and/or sepsis. Therefore this agent should be employed only after UTI and/or colonization has been brought under control. Chemolysis with various agents is no longer routinely used for the management of struvite calculi.

Acetohydroxamic acid, a urease inhibitor, may reduce the urinary saturation of struvite and therefore retard stone formation (Griffith et al, 1978). When given at a dose of 250 mg three times per day, acetohydroxamic acid has been shown to prevent recurrence of new stones and inhibit the growth of stones in patients with chronic urea-splitting infections. At least two studies have demonstrated significant efficacy in randomized, placebo controlled trials (Williams et al, 1984; Griffith et al, 1991). In these investigations, patients were treated with acetohydroxamic acid and antibiotics. Recurrence rates and subsequent stone growth were significantly less for patients treated with drug therapy compared to placebo. In addition, in a limited number of patients, this agent has caused dissolution of existing struvite calculi (Rodman et al, 1983). However, a significant percentage of patients receiving chronic acetohydroxamic acid therapy have experienced minor side effects and 15% developed deep venous thrombosis. Indeed, Rodman and colleagues (1987) demonstrated that patients receiving acetohydroxamic acid enter into a state of low-grade intravascular coagulation requiring careful follow-up for signs of thrombosis. Several authors reported high rates of medication cessation because of intolerable side effects. In the previously noted randomized studies, 22% to 68% of treated patients had to stop therapy and withdraw from the investigation. Reported side effects have been varied and include thromboembolic phenomena, tremor,

headache, palpitations, edema, GI distress, loss of taste, rash, alopecia, anemia, and abdominal pain. Because of these concerns, this agent is frequently reserved for patients deemed too ill for surgical management. Other acidifying agents have been reported by [Wall and Tiselius \(1990\)](#) but do not appear to have been widely used. These include ammonium chloride, methenamine hippurate, and ascorbic acid.

Controversy exists as to whether patients with infection stones warrant metabolic evaluation with 24-hour urine collections. In one study, only 14% of patients with a pure struvite stone had a metabolic abnormality on 24-hour urine collection. Of the patients who had a mixed struvite stone, 100% had a metabolic abnormality ([Lingeman et al, 1995](#)). A more recent retrospective review found that three in five patients with a pure struvite stone had a metabolic abnormality on 24-hour urine collection. Two of the patients were found to have hypercalciuria, one patient had hypocitraturia, and one patient had hyperoxaluria. Of the patients with mixed struvite stones, 77% had a metabolic abnormality. The authors found that with appropriate medical management of both the metabolic abnormalities and the UTI with either acetohydroxamic acid and/or suppressive antibiotics, 60% of patients with residual stone demonstrated no stone growth at a median follow-up of 22 months ([Iqbal et al, 2013](#)). Therefore there may be some value in performing 24-hour urine collections in patients with struvite stones and appropriately managing their metabolic abnormalities.

KEY POINTS: INFECTION LITHIASIS

- Struvite calculi are best managed with surgical removal rather than chemical dissolution.
- Recurrent infections (and therefore recurrent calculi) may be avoided with the use of antibiotic prophylaxis.
- Acetohydroxamic acid (Lithostat) can effectively inhibit urease, but its widespread use is precluded by significant side effects.

Ammonium Acid Urate Stones

Ammonium acid urate calculi are infrequently seen in industrialized nations and are often associated with laxative abuse ([Dick et al, 1990](#); [Kato et al, 2004](#)). The largest described series was reported in 1999 ([Soble et al, 1999](#)). In this series, 23 women and 21 men ranging in age from 20 to 81 years (mean 48.7 years) were treated for stones partly composed of ammonium acid urate. Stone composition ranged from 2% to 60% ammonium acid urate (mean 24.1%) of the total stone mass. No patient had a pure ammonium acid urate stone, although 11 (25%) had stones with ammonium acid urate as the predominant crystal. The authors identified one or more potential risk factors for ammonium acid urate for most patients. Of the patients, 25% had a history of inflammatory bowel disease, with 22.7% having undergone ileostomy diversion, 13.6% admitted to a history of significant laxative use or abuse, 40.9% were morbidly obese, 36.4% had a history of recurrent UTIs, and 20.5% had a history of recurrent uric acid stones. Based on these findings, the authors suggested that laxative abuse should not be assumed for all patients with ammonia acid urate calculi, but rather conditions resulting in metabolic acidosis, the prime risk factor for urate stones. Therefore a full history and metabolic evaluation should be sought for each patient.

Medical treatment for these calculi is determined by the underlying cause of the stone. Those with laxative abuse are strongly encouraged to develop a healthier bowel regimen. Those with chronic infections are treated much like those with struvite calculi. Bowel disease is treated, if possible, while standard recommendations of fluid intake, oral calcium, alkalization, and oxalate reduction are made. Those with a history of uric acid calculi are also treated in a similar manner with increased fluid intake, protein and salt restriction, alkalization with potassium citrate, and the possible use of allopurinol.

Miscellaneous and Drug-Induced Stones

Some stones are formed from supersaturation of the medications themselves or may be due to the effects of a particular agent. Several medications have been associated with stone disease and are listed in [Box 52-6](#).

Calculi formed from antiretroviral medications used to treat human immunodeficiency virus (HIV) have been described, particularly with indinavir (Crixivan) ([Bach and Godofsky, 1997](#); [Hug et al, 1999](#); [Sundaram and Saltzman, 1999](#); [Saltel et al, 2000](#)). These calculi can be quite soft and often dissipate rapidly during endoscopy or shock wave lithotripsy. Difficulties may arise during diagnosis—indinavir stones may not be visible on plain film radiography and even may be undetectable on a stone protocol CT ([Gentle et al, 1997](#); [Sundaram and Saltzman, 1999](#)). Treatment entails aggressive hydration and endoscopy for stones that do not pass spontaneously. The radiolucency of the calculi often precludes successful treatment with shock wave lithotripsy. In the short term, patients may be temporarily taken off of indinavir until an aggressive fluid habit can be established. Some patients require cessation of this antiretroviral drug and the initiation of a different agent.

As described earlier, triamterene, a potassium-sparing antihypertensive agent may crystallize in the urinary tract, requiring cessation of this medication ([Werness et al, 1982](#); [Sorgel et al, 1985](#)). For this reason, triamterene is not recommended as an adjunct to thiazides during the treatment of hypercalciuric states.

Carbonic anhydrase inhibitors may be associated with the formation of calcium-based calculi, particularly calcium phosphate ([Kondo et al, 1968](#); [Parfitt, 1969](#)). In this scenario, the use of the medication creates a chronic intracellular acidosis. This effect in turn creates a urinary milieu reminiscent of a distal tubular acidosis with hyperchloremic acidosis, high urine pH, extremely low urinary citrate, and hypercalciuria. Treatment may be accomplished with potassium citrate replacement or, more logically, cessation of the medication.

Topiramate is prescribed for the treatment of refractory epilepsy and recurrent migraine headaches and was recently approved for weight loss. Unfortunately, it may mimic the effect of a carbonic anhydrase inhibitor with resultant metabolic acidosis, hypocitraturia, hypercalciuria, and elevated urine pH ([Kossoff et al, 2002](#); [Kuo et al, 2002](#); [Lamb et al, 2004](#)). Potassium citrate has been shown to restore urinary citrate and prevent recurrent stone disease ([Vega et al, 2007](#); [Warner et al, 2008](#); [McNally et al, 2009](#); [Kaplan et al, 2011](#)).

Finally, multiple authors have described calculi that have formed in patients taking over-the-counter supplements containing ephedrine ([Blau, 1998](#); [Powell et al, 1998](#); [Assimos et al, 1999](#);

BOX 52-6 Medications Associated with Renal Calculus Formation

CALCULI FORMED FROM DRUG

Indinavir
Ephedrine
Triamterene
Magnesium trisilicate antacids (silicates)
Trimethoprim-sulfamethoxazole

CALCULI PROVOKED BY DRUG

Carbonic anhydrase inhibitors
Topiramate
Furosemide
Vitamin C (excess)
Vitamin D (excess)
Laxatives

Hoffman et al, 2003; Bennett et al, 2004; Smith et al, 2004; Whelan and Schwartz, 2004). These calculi are likely radiolucent, but have been reported to be “visible” on noncontrast CT. Ephedrine stones have been treated with a variety of methods, including shockwave lithotripsy, endoscopy, and even alkalization therapy. Because this supplement has a risk for abuse, it may be difficult to effectively interfere with the formation of future stone events.

MISCELLANEOUS SCENARIOS

Medical Management of Bladder Calculi

In the United States, bladder calculi usually occur in men older than 50 years of age and are usually associated with bladder outlet obstruction. The diagnosis of a bladder stone should result in a complete urologic evaluation for factors that cause urinary stasis, such as urethral stricture, benign prostatic hyperplasia, bladder diverticulum, and/or a neurogenic bladder. Occasionally, bladder stones may result as a consequence of a retained foreign body.

In contrast to renal stones, bladder stones are usually composed of uric acid (in noninfected urine) or struvite (in infected urine). Reports from the United States revealed uric acid stones in nearly 50% of patients with bladder stones (Douenias et al, 1991). Such patients often have bladder outlet obstruction, causing them to decrease fluid intake with the resultant production of concentrated acidic urine. The occurrence of calcium oxalate or cystine stones in the bladder suggests the presence of calculi in the kidney with subsequent ureteral passage and entrapment in the bladder.

Bladder calculi are usually solitary, but may develop in large numbers in the presence of urinary stasis (Sarica et al, 1994). The typical symptoms of a vesical stone are intermittent, painful voiding and terminal hematuria. Discomfort may be dull, aching, or sharp suprapubic pain, which is aggravated by exercise and sudden movement. Severe pain usually occurs near the end of micturition, when the stone becomes impacted at the bladder neck. Relief may be afforded by assuming a recumbent position. The pain may be referred to the tip of the penis, the scrotum, or the perineum and on occasion to the back or the hip. Besides pain, there may be an interruption of the urinary stream from impaction of the stone at the bladder neck or urethra.

Bladder calculi are frequently missed on plain film because of a high component of uric acid and because of overlying prostatic tissue. Such stones form negative shadows in the cystogram phase of intravenous urography. Ultrasonography is useful for detecting radiolucent calculi. Cystoscopic examination is the surest method for detecting vesical calculi.

The vast majority of bladder calculi can be removed via endoscopic techniques. Various lithotripters have been used, including ultrasonic handpieces, lasers, pneumatic devices, and electrohydraulic probes. Transurethral and percutaneous approaches have been described with good success (Dhabalia et al, 2011; Philippou et al, 2011). Renacidin may prove beneficial in irrigating indwelling suprapubic or urethral catheters to decrease and prevent encrustation and occlusion (Kennedy et al, 1992; Getliffe et al, 2000). Twice-daily or thrice-daily irrigation with 0.25% or 0.5% acetic acid solution also serve as beneficial prophylaxis against recurrent struvite calculi when catheters must be left indwelling for long periods. Uric acid calculi may be dissolved by irrigation with alkaline solutions.

The mainstay of therapy for the prevention of recurrent bladder calculi involves relief of the bladder outlet obstruction. This treatment may include the performance of a transurethral resection of the prostate or an open prostatectomy if the gland is quite large.

Medical Management of Pediatric Calculi

Children may develop urinary calculi because of several underlying causes, as outlined in Chapter 51. Evaluation and management depend on the causative process.

Neonatal Nephrolithiasis

Neonates with furosemide-induced nephrolithiasis present with hematuria, worsening renal function, and calcific densities on ultrasonography or plain film radiography. Nephrocalcinosis is often present on imaging studies. This same process has been seen in other infants with severe low birth weight and/or prematurity and no history of loop diuretic usage.

Management of neonatal nephrolithiasis entails the obvious optimization of the infant's overall health. Cessation of furosemide diuresis is considered helpful and standard therapy. There has been previous suggestion that treatment with thiazide diuretics may actually promote the resolution of this process and reverse the likely parenchymal injury (Noe et al, 1984). This observation has not been supported by other investigators, however. Pope and colleagues (1996) noted a 50% resolution rate of the nephrocalcinosis after cessation of loop diuretics, but this finding was unrelated to any other factor, including the use of thiazides. Instead, a low calcium-to-creatinine ratio at the time of diagnosis was the best predictor of resolution. Further research by Knoll and Alon (2000) using an animal model of the disease did not demonstrate a therapeutic effect of the use of thiazides on furosemide-induced nephrocalcinosis.

At the very least, this evidence suggests that neonates treated with loop diuretics should be screened for the development of nephrocalcinosis. Although switching to a thiazide diuretic may not actively cause the dissolution of calculi, it at least removes the causative agent and allows the kidney an opportunity to heal and clear the calcium deposits.

Children and Adolescents

As children reach physical maturity at a younger age, it is not surprising that the incidence of urinary calculi in adolescence appears to be increasing. Within the United States this finding is likely further related to the increasing prevalence of obesity within this same age group. Nevertheless, the appearance of urinary calculi during childhood should raise the distinct possibility of an inherited genetic disorder, such as cystinuria, distal RTA, or primary hyperoxaluria.

The evaluation of pediatric nephrolithiasis has been hampered in the past by a lack of consensus regarding normal laboratory values during 24-hour urine collections in children. Clinicians have therefore relied on calculated ratios to correct for the wide variation in weight within this diverse patient population. The most important of these has been the urinary calcium-to-creatinine ratio. A calculated urinary calcium-to-creatinine ratio above 0.2 has been considered abnormal and frequently prompts intervention.

Several investigators have explored the use of urinary supersaturation calculations to assess for stone risk factors in children (Battino et al, 2002; Lande et al, 2005). These calculations may miss abnormalities otherwise overlooked by traditional cumulative measurements. At least one of these authors, however, notes that the importance of supersaturation wanes considerably in the face of low urine volumes (Lande et al, 2005).

Evidence strongly supports close and aggressive follow-up of pediatric stone formers. Pietrow and associates (2002) found that 50% of children 10 years or younger with urinary calculi have an identifiable metabolic derangement. Additionally, those with abnormal urinary metabolites are five times more likely to have recurrent stones. However, the identification of these abnormalities is more challenging in the pediatric population. Reference values for this population are not as well defined and may require adjustments based on body weight and urinary creatinine level to best delineate abnormalities (Borawski et al, 2008).

The medical management of nephrolithiasis and the prevention of subsequent recurrences in children do not differ that dramatically from the approaches undertaken for adults. All patients (and their parents) are counseled to improve fluid intake. Dietary recommendations are similar to those made for

adults. It is important to emphasize that dietary calcium is not to be avoided in this age group. Rather, calcium should be sought through the ingestion of dairy and other natural sources rather than with the use of supplements. Such sources will also bind dietary oxalate during meals and may decrease calcium oxalate supersaturation in the urine.

Children with cystinuria or hyperoxaluria are managed as outlined in the previous section within this chapter. The exception to this would be a general reticence to begin sulfur-binding agents in cystinuric children, without first maximizing fluid intake and the use of citrates to alkalinize the urine.

Children with documented hypocitraturia and/or distal RTA are usually treated with citrates at a dose of 4 mg/kg/day (Domrongkitchaiporn et al, 2002a). Hypercalciuria may respond to increased fluid intake and decreased sodium (salt) ingestion, much like the adult population. Thiazides may be employed for recalcitrant hypercalciuria. The long-term efficacy and safety of thiazides in the pediatric population has not been well studied and established.

Medical Management of Calculi during Pregnancy

The management of calculi during pregnancy is currently undergoing a transformation. These changes, however, are developing mainly within the realm of surgical intervention, not medical therapy. As noted in Chapter 51, pregnant women create a unique urinary environment that is prone to stone formation. Although the amount of urinary calcium rises quite notably (Gertner et al, 1986), this effect is offset by an accompanying increase in urinary citrate. As a result, it is widely assumed that there is no net increase or decrease in the risk for calculi formation during pregnancy (Coe et al, 1978; Maikranz et al, 1987). As a result of these temporary physiologic changes, a metabolic evaluation is not generally undertaken to determine the cause of the stone disease until after the woman has delivered and returned to her baseline state of health.

Patients with a history of stones should be strongly encouraged to maintain high fluid intake. Dietary recommendations should be reinforced. Patients who have previously undergone metabolic evaluation and are on medical therapy should be informed about the compatibility of their medications with pregnancy.

The acute evaluation of a pregnant woman with suspected renal colic begins with a thorough history and physical examination. A urinalysis is obtained and examined for signs of active UTI. Patients may present with vague abdominal pain, unexplained fevers, recurrent UTIs, persistent bacteriuria, or microscopic hematuria. A previous history of nephrolithiasis should be sought because the increased dilation of the ureters during pregnancy may increase the risk that a preformed stone will break loose and attempt to pass.

Radiation exposure to the fetus should be avidly avoided. Therefore ultrasonography has become the first-line imaging study to search for calculi during pregnancy. Although this modality provides adequate images of the kidneys, it can be difficult to fully discern the ureters and their contents. Additionally, hydronephrosis of pregnancy may be confused for hydronephrosis from an obstructing calculus. A limited intravenous pyelogram (IVP) may be obtained that consists of one scout image followed by one plate taken approximately 30 minutes after the injection of contrast. Each plain film exposes the fetus to 0.1 to 0.2 rads, well below the threshold of 1.2 rads, at which the risk begins to increase. Radiation exposure should be particularly avoided during the first trimester during the time of organogenesis and the greatest fetal risk.

In keeping with the concern of fetal radiation exposure, assessment of a low-dose CT protocol was performed (White et al, 2007). The average radiation exposure was 0.7 rads (0.2 to 1.3 rads). Of the 20 patients evaluated for flank pain, 13 were identified as having urinary stones ranging from 1 to 12 mm. Magnetic resonance imaging (MRI) has also been reported for stone diagnosis in pregnant patients (Mullins et al, 2012). A report comparing the effectiveness of different imaging modalities during pregnancy found a 23% rate of negative ureteroscopy for a presumed stone when

ultrasound alone was used for diagnosis (White et al, 2013). This is compared to a 4.2% negative ureteroscopy rate when CT was used and a 20% negative ureteroscopy rate when MRI was used.

Approximately 66% to 85% of pregnant women with ureteral colic spontaneously pass the calculi when treated conservatively with hydration, analgesics, and, if infected, antibiotics (Jones et al, 1979; Stothers and Lee 1992). The goal of therapy for the remaining patients is to do the least required to keep the kidney functioning, the patient free from symptoms, and the urine uninfected. Stents should be placed cystoscopically with minimal radiographic or sonographic monitoring (Loughlin and Bailey, 1986; Jarrard et al, 1993). Because many expectant mothers take calcium supplementation, a more stone-friendly form of this mineral has been developed (Citracal Prenatal Rx; Mission Pharmaceutical, San Antonio, TX). In this formulation, calcium is bound to citrate, which delivers extra stone inhibitor into the urine and thereby offsets the effects of worsening absorptive hypercalciuria. Iron and folate are also added to complete the elements commonly found in prenatal multivitamin supplements. Although there are no randomized data to support the use of this supplement in pregnant women, its use does make intuitive sense for patients at risk for recurrent calculi during pregnancy.

KEY POINTS: MEDICAL MANAGEMENT OF CALCULI

- Bladder calculi are best managed with endoscopic techniques. Subsequent recurrence is prevented by relief of the bladder outlet obstruction.
- Neonatal nephrocalcinosis is frequently caused by loop diuretics. Cessation of this medication is essential.
- Neonatal nephrocalcinosis may be reversed by the use of thiazides.
- The majority of ureteral calculi during pregnancy pass spontaneously.
- There is a growing trend toward endoscopic relief of symptomatic calculi during pregnancy.

SUMMARY

Appropriate metabolic evaluation and selective medical therapy of nephrolithiasis is highly effective in preventing new stone formation. A remission rate of greater than 80% and overall reduction in individual stone formation rate of greater than 90% can be obtained in patients with nephrolithiasis. In patients with mild-to-moderate severity of stone disease, virtually total control of stone disease can be achieved, with a remission rate of greater than 95%.

Selective pharmacologic therapy of nephrolithiasis also encompasses the advantages of overcoming nonrenal complications, as well as averting certain side effects that may be caused by nonselective medical therapy. Despite these advantages, it is clear that selective medical therapy cannot provide total control of stone disease. A satisfactory response requires continued, dedicated compliance by patients to the recommended program and a commitment of the physician to provide long-term follow-up and care.

Historical Overview

Renal Calculi

Ureteral Calculi

HISTORICAL OVERVIEW

Please see the Expert Consult website for details.

RENAL CALCULI

One of the core tenets of renal stone surgery is to maximize stone removal while minimizing attendant morbidity to the patient. Before the era of endourology, stones were removed via open stone surgery, which provided high stone-free rates but came with a high rate of complications. In the early 1980s, SWL was developed and proved to have an excellent safety profile while achieving acceptable stone-free rates. During the same time period, PCNL was developed and refined such that it is now considered the gold standard for large and complex kidney stone disease for most patients. Over the last two decades as the technology has improved and the surgical technique diffused, URS has been used with increasing frequency in the treatment of renal stones. More recently, in experienced hands, it has been demonstrated that laparoscopic and robotic-assisted renal stone surgery can be safely used in selected patients with good outcomes. In areas where endourologic technology is widely available, open stone surgery is pursued only 1% of the time or less, and even in developing countries open stone surgery rates have dropped dramatically from 26% to 3.5% (Paik and Resnick, 2000; Honeck et al, 2009).

Thus, for most urologists the armamentarium to surgically treat kidney stones consists of four minimally invasive modalities including SWL, URS, PCNL, and laparoscopic or robotic-assisted stone surgery. Staged procedures of a given modality and combinations of different modalities (i.e., “sandwich technique” using SWL and PCNL, and SWL and URS) have been described as well. There appears to be an evolving paradigm shift in the surgical treatment of upper tract stones, with an increasing use of URS and a reciprocal decreasing use of SWL (Lee and Bariol, 2011; Ordon et al, 2014).

Deciding on the optimal treatment for a given patient is not always clear and depends on many variables, which can be broadly lumped into stone-related factors, renal anatomic factors, and clinical factors (Box 53-1). The combination of these factors, availability of technology and equipment, and familiarity of the urologist with the different surgical techniques ultimately determines which treatment is preferred for a given patient. The purpose of this section is to provide a framework to help guide the urologist in matching a given patient's unique clinical situation and renal stone disease characteristics to the most effective and least morbid surgical therapy (Fig. 53-1).

Natural History

The incidence of asymptomatic renal stones has been reported in approximately 10% of screened populations. In one evaluation of just over 5000 patients undergoing screening computed tomography (CT) colonography, asymptomatic urinary stones were found in 7.8% of patients, with a mean size of 3 mm and an average of two stones per patient (Boyce et al, 2010). In another study evaluating almost 2000 potential kidney donors, asymptomatic renal stones were found in 9.7% of patients (Lorenz et al, 2011). It is interesting to note that the true natural history of renal calculi, in particular asymptomatic renal calculi, has not been well characterized. Treatment is generally recommended for symptomatic stones, including those associated with pain, infection, obstruction, active stone growth, and significant hematuria. However, the available evidence is less clear on how to approach minimally symptomatic or asymptomatic renal calculi.

Before the era of minimally invasive stone treatments, asymptomatic and minimally symptomatic stones were not actively removed, given the high morbidity associated with treatment. Currently, with the expanding availability of SWL and URS, treatment of small stones can be offered with low surgical morbidity. Although some small, asymptomatic renal stones may never require treatment, a review of the known behavior of such stones suggests that many will grow over time, become symptomatic, and ultimately require treatment.

Nonstaghorn Renal Calculi

A number of studies have reviewed the fate of asymptomatic renal stones while under observation; however, the longest follow-up for any of these series is approximately 10 years, with the majority of them following patients for less than 5 years. Thus the true natural history of asymptomatic renal stones over an extended time period is unknown. Most studies evaluating this type of stone presentation report the rate of spontaneous passage, the rate of intervention, and the rate of stone progression, often defined as stone growth, development of symptoms, or need for intervention.

Hubner and Porpacz (1990) reviewed the natural history of renal stones in 62 patients managed before the advent of SWL or widespread URS. Of this cohort, spontaneous passage was seen in 16%, whereas 40% required surgical intervention. Stone growth was noted in 45% of patients, urinary tract infection (UTI) occurred in 68%, and pain developed in 51%. Similar results were found by Glowacki and colleagues (1992), with 32% of initially asymptomatic renal stones becoming symptomatic. Of these patients, half (15%) spontaneously passed their stones, and the calculated 5-year

Kidney Calculi

Although calculi in the kidney were rare before the Industrial Revolution (Shah and Whitfield, 2002), the existence of nephrolithiasis was known to Hippocrates, who described the symptoms of renal colic: "An acute pain is felt in the kidney, the loins, the flank and the testis of the affected side; the patient passes urine frequently; gradually the urine is suppressed. With the urine, sand is passed." It is not certain whether Hippocrates actually performed surgery on patients with renal calculi, but he did describe the following operations: the drainage of tuberculous and nontuberculous pyelonephritic abscesses, the incision of swelling in the loin caused by renal tumefaction resulting from stone, and the drainage of kidneys with acute congestion caused by pyelonephritis (Wershub, 1970). In the centuries that followed Hippocrates, there was little scientific progress in the surgical therapy for patients with renal calculi. The alleged first account of a surgical attempt to remove a stone from a patient's kidney is the case of the French archer of Bagnolet. Little is known of the authenticity of this tale of a condemned man with a renal calculus who agreed to allow surgery on the affected kidney with the condition that if he survived he would be freed. According to the anecdote, the man survived the open surgical stone removal and was freed in 1474 (Herman, 1973). Unfortunately, there are no first-hand records of this event. The first verifiable account of renal stone surgery was in 1550, when Cardan of Milan opened a lumbar abscess on a young girl and removed 18 calculi (Desnos, 1972). For the next two centuries, most surgeons were in agreement that the only indication for open renal surgery was the infected calculus kidney, distended by the accumulation of purulent matter, or those kidneys in which the calculus could be palpated in the organ itself.

In 1734 Lafite incised a swelling in a patient's loin and drained considerable purulence. Twenty-two days later the pus reaccumulated; he probed the incision and found a stone in the region of the kidney. Lafite widened the prior incision and removed two calculi; the patient recovered well. Four years later Lafite again removed stones from a man who had undergone drainage of a lumbar swelling 11 years before and who had a persistent urinary fistula. Lafite concluded that it was possible to remove the stones at the time of the first surgical intervention rather than subject the patient to multiple procedures (Ballenger et al, 1933). In 1872, William Ingalls of Boston City Hospital removed a large calculus from the right kidney of a 31-year-old woman with a persistent pyelocutaneous fistula (Spirnak and Resnick, 1983). Ingalls incised the sinus tract of the fistula and extracted the stone with forceps, thus performing the first recorded nephrolithotomy in America. In 1880, Henry Morris of England was the first to remove a stone from an otherwise healthy kidney by nephrolithotomy, extracting a 31-g mulberry calculus from the kidney of a young woman (Dudley, 1973).

As the surgical techniques of nephrolithotomy evolved, renal parenchymal incisions were made in a variety of different ways in an effort to reduce hemorrhagic morbidity. Heineke in 1879 first described a pyelotomy incision for the extraction of calculi. The operation rapidly found favor and was used by many surgeons, although it was not possible to extend the incision to permit extraction of large renal calculi without damaging the retropelvic renal artery (Wershub, 1970). Josef Hyrtl in 1882 and Max Brödel in 1902 described a relatively avascular plane near the midline (5 mm posterior) of the convex border of the kidney through which the collecting system of the kidney could be entered. In continental Europe, credit for the plane was given to Hyrtl; but in England and the United States it was called the *Brödel bloodless line* or the *Brödel white line* (Schultheiss et al, 2000). Although the existence of this avascular plane was an important discovery, surgeons continued to find that bleeding during nephrolithotomy was a considerable problem. Zuckerkandl described an inferior pyelonephrolithotomy in which a pyelotomy incision was extended into the lower pole of the kidney. Partner recommended a V-shaped incision with two limbs radiating toward the poles of the kidney. Other attempts were made to control the persistent problem of bleeding, including compres-

sion of the hilar vessels and various methods of suturing. In 1887, Czerny was the first to approximate the cut edges of the incised kidney with suture to control hemorrhage and to prevent fistula formation. In the same year, Guyon reported that nephrectomy, although efficacious in curing patients with calculus pyonephrosis, was more dangerous than nephrolithotomy because lithiasis was often bilateral (Wershub, 1970). In 1889 Kümmell was the first surgeon to perform a partial nephrectomy for calculus pyonephrosis (Redman, 1983). Lower, in 1913, revived interest in pyelolithotomy when he suggested that this technique might be a safer and easier method of removing renal calculi than nephrolithotomy. Although several small series of cases indicated that there might be a higher incidence of stone recurrence after pyelolithotomy, other studies showed that recurrence was no more common than it was after nephrolithotomy (Murphy, 1972). These findings, in conjunction with rapid advancements in the field of radiography, brought about a decided preference for pyelolithotomy (Gil-Vernet and Culla, 1981). In 1943 Dees and Fox reported the first use of coagulum to remove small stones and stone fragments from the renal pelvis and calyces (Marshall, 1983). Fibrinogen and thrombin were used to make a coagulum that was injected into the renal pelvis and produced a flexible cast of the pelvis and calyces. The use of this technique was limited initially owing to the scarcity of materials and the risk of blood-borne disease transmission. However, interest in coagulum pyelolithotomy was renewed when cryoprecipitate was found to be a safe and readily available source of concentrated fibrinogen (Fischer et al, 1980).

An important advance in the open surgical approach to the kidney was the intrasinusally extended pyelolithotomy, pioneered by Gil-Vernet in 1965. Because of its wide applicability and minimal morbidity, this approach to the renal collecting system became the procedure of choice for treatment of the majority of renal pelvic calculi. Patients harboring large or complex calculi could be effectively treated with extended pyelolithotomy combined with multiple radial nephrotomies (Wickham et al, 1974). In 1968 Smith and Boyce described *anatomic nephrolithotomy*, a procedure that derived its name from the technique of incising the renal parenchyma along the avascular plane between the anterior and posterior vascular distributions. Because an incision in this plane does not interrupt the blood supply to the renal parenchyma, it does not result in atrophy, hence the term *anatomic*. This procedure permits a relatively bloodless operation that encompasses stone removal, reconstruction of the calyceal system, and closure of the renal capsule with preservation of renal function. Although stone-free rates of these modern surgical techniques were excellent, morbidity was significant, and the search for new techniques and technologies continued.

Ureteral Calculi

Ambroise Paré is credited with the first account of a ureteral calculus, when, in 1564, he described "the cruel pain [that] tormented the patient in that place where the stone lodged." Paré also stated that death was the consequence of having calculi impacted in both ureters (Murphy, 1972). Morris recounted that surgical intervention was an option in the treatment of ureteral stones when he reported in 1898 that "operations on the ureter are an advance of the last few years, but not many have been recorded up to the present time" (Ballenger et al, 1933). Thomas Emmet of New York published an account in 1879 of three female patients with stones impacted at the distal aspect of the ureter. In one patient Emmet opened the bladder and removed the stone with forceps; in a second patient he removed a stone by cutting down on it through the vaginal wall. These procedures were the first records of a surgeon making a definite diagnosis of ureteral calculus and deliberately and successfully performing a ureterolithotomy. In the years that followed, intraperitoneal, perineal, sacral, transrectal, and transvaginal approaches were used. In 1910, Gibson of New York described an incision parallel to and just above the Poupart ligament, wholly extraperitoneal, by which the lower ureter, even down to its entrance into the bladder, could be readily exposed. This safe and comparatively

easy approach to the ureter gave open ureterolithotomy a solid basis for success.

The Rise of Endourology

Before the development of endoscopy, attempts to blindly extract calculi were not uncommon. In 1889, Gustav Kolisher performed the first successful stone manipulation, reporting that he “located the stone with a metal-tipped catheter several inches above the ureteric orifice and through it injected 30 cc of sterile oil,” displacing the stone (Murphy, 1972).

The development of minimally invasive surgical techniques for the treatment of patients with urinary lithiasis has been greatly dependent on technologic advances in the fields of **fiberoptics**, **radiographic imaging**, and **lithotripsy** (shock wave, ultrasonic, electrohydraulic, and laser). These advancements have accelerated the evolution of modern techniques of calculus removal, including **ureterorenoscopy** (URS), **percutaneous nephrolithotomy** (PCNL), and **extracorporeal shock wave lithotripsy** (SWL). In 1979, Arthur Smith defined the term *endourology* as closed controlled manipulation within the genitourinary tract (Smith et al, 1979).

Ureterorenoscopy

The practice of URS began by happenstance when in 1912 Hugh Hampton Young introduced a pediatric cystoscope into the massively dilated ureter of a child with posterior urethral valves (Young and McKay, 1929). Aided by the child's secondary ureteral dilation, Young was able to advance the cystoscope to the level of the renal pelvis, thus becoming the first urologist to view the intrarenal collecting system endoscopically. Unfortunately the following three decades held few significant advances in ureteroscopic technology until knowledge of fiberoptics could be put to clinical use. By 1957, Curtiss and Hirschowitz combined a large number of glass fibers into a coherent bundle and fused the fibers at their ends to allow them to move individually along their length, thus creating the first flexible endoscope (Hirschowitz et al, 1957). In 1964, Marshall reported the first urologic use of this new type of flexible endoscope when he passed the scope through an open ureterotomy to the level of the renal pelvis, thereby performing the first flexible URS. Subsequently, two of his associates, McGovern and Walzak, performed the first transurethral flexible URS when they passed the same 9-Fr flexible endoscope to inspect a ureteral calculus. Since then, developments in optics and mechanics have greatly improved the design of flexible ureteroscopes.

Currently available ureteroscopes range from 54 to 70 cm in length and have a tapered shaft diameter that increases proximally. As the tip of the ureteroscope is inserted into the ureter and passed retrograde, the ureter is slowly dilated. Initial ureteroscopes had neither a working nor an irrigating channel. Most modern ureteroscopes have a single working channel, and some have a second irrigation channel that serves to distend the ureter and maintain visualization.

Early flexible ureteroscopes were passive, and the subsequent incorporation of active tip deflection has greatly increased their usefulness. *Active deflection* refers to deflection of the tip of the endoscope, which is controlled by the surgeon through a lever mechanism on the handle of the endoscope. Flexible ureteroscopes have been introduced with two segments of active deflection, with the active primary site of deflection providing 170 to 180 degrees of up-and-down movement; the secondary active deflection, located several centimeters proximal to the primary deflection, is a 130-degree one-way downward deflection. This design greatly facilitates entry into the lower pole infundibulum. Other manufacturers have designed flexible ureteroscopes with 270 degrees of deflection, which also facilitates entry into the lower pole infundibulum.

More recently, efforts have been devoted to advancing the imaging capability of the flexible ureteroscope. Digital endoscopes, which incorporate an optical chip (complementary metal-oxide semiconductor [CMOS] or charge-coupled device [CCD]) at the tip have been introduced. Although the initial generation of these chips

were quite large, further refinements have reduced their size so that they can be applied to flexible ureteroscopes. Advantages associated with this technology include improved optical characteristics, obviating focus and white-balancing issues, and decreased surgeon fatigue, because cumbersome proximal camera and light cord attachments are not required. Image-processing software permits digital zoom capability as well. In comparing digital flexible URS with conventional fiberoptic flexible URS, investigators have noted that the digital devices are associated with superior imaging characteristics (Humphreys et al, 2008). Disadvantages of the digital device must be recognized, however: Digital ureteroscopes are larger in diameter than their fiberoptic counterparts, and the technology also is more costly.

It is interesting to note that the first reports of rigid URS trailed those of flexible URS by almost 10 years. In 1977 Goodman reported on three cases in which a pediatric cystoscope was used to treat patients with ureteral malades. These initial rigid ureteroscopes used a rod-lens system that was large (10 to 13 Fr) and inflexible. Most rigid ureteroscope designs have replaced this rod-lens system of image transmission with fiberoptics, which allows significant reduction in the size of the endoscope. In addition, the flexibility of the fiberoptic bundles allows the shaft of the endoscope to become somewhat bendable along its vertical axis, hence the term *semirigid ureteroscope*.

Parallel to improvements in rigid and flexible ureteroscopes were advances in intracorporeal lithotripters, including ultrasonic, electrohydraulic, pneumatic, and laser probes, allowing efficient stone fragmentation through the miniaturized modern ureteroscopic equipment. Many new stone-retrieval devices, designed to pass through the working channel of a ureteroscope, have been introduced with the capability for manipulation and deflection.

Percutaneous Stone Removal

The first description of percutaneous stone removal was that of Rupel and Brown (1941) of Indianapolis, who removed a stone through a previously established surgical nephrostomy. It was not until 1955, however, that Goodwin and associates described the first placement of a percutaneous nephrostomy tube to drain a grossly hydronephrotic kidney. These researchers did not have the benefit of radiographic guidance, and so the drainage tube was placed without imaging. In 1976, Fernstrom and Johansson first reported the establishment of percutaneous access with the specific intention of removing a renal stone. Subsequent advances in endoscopes, imaging equipment, and intracorporeal lithotripters allowed urologists and radiologists to refine these percutaneous techniques through the late 1970s and early 1980s into well-established methods for removal of upper urinary tract calculi.

Extracorporeal Shock Wave Lithotripsy

The phenomenon that sound waves can be focused has been known since antiquity. The ancient Greeks, as taught by Dionysius, used this knowledge to construct vaults that allowed them to overhear the conversations of their imprisoned enemies. In the 18th and 19th centuries, cabinets constructed with echo or sound mirrors were capable of transmitting the ticking of a pocket watch over a distance exceeding 60 feet.

High-energy shock waves, too, have been recognized for many years. Examples of high-energy shock waves include the blast effect associated with explosions, as well as the potentially window-shattering sonic boom created when aircraft pass beyond the speed of sound. Engineers at Dornier Medical Systems in what was then West Germany, during research on the effects of shock waves on military hardware, demonstrated that these shock waves are reflectable and therefore focusable. The possibility of applying shock wave energy to human tissue was discovered when, by chance, a test engineer touched a target body at the very moment of impact of a high-velocity projectile. The engineer felt a sensation similar to an electric shock, although the contact point at the skin showed no damage at all (Hepp, 1984). This observation and its potential

military applications led Dornier to pursue a method of generating a reproducible shock wave.

Beginning in 1969 and funded by the German Ministry of Defense, Dornier began a study of the effects of shock waves on tissue. Specifically, the study was to determine if the shock waves generated by a projectile striking the wall of a military tank would damage the lungs of a crew member leaning against the same wall. During the study, Dornier engineers developed techniques to reproducibly generate shock waves. In the course of this effort the engineers discovered that shock waves generated in water could pass through living tissue (except for the lung) without discernible damage to the tissue but that brittle materials in the path of the shock waves would be fragmented.

At some point a possible medical application of shock waves became apparent: If shock waves could safely pass through tissue but fragment brittle materials, perhaps they could be used to break up kidney stones. Dornier engineers found that lower-energy shock waves, which would be appropriate for medical applications, could be generated in a predictable and reproducible manner by an underwater electrical spark discharge.

In 1972, on the basis of preliminary studies performed by Dornier Medical Systems, an agreement was reached with Egbert Schmiedt, director of the urologic clinic at the University of Munich, to proceed with further investigation of the therapeutic potential of this technology ([Chaussy and Fuchs, 1986, 1989](#)). This research was supported by the West German Federal Ministry of Research and Technology, and the development of the Dornier lithotripter progressed through several prototypes, ultimately culminating in February 1980 with the first treatment of a human by SWL. The production and distribution of the Dornier HM3 lithotripter began in late 1983, and SWL was approved by the U.S. Food and Drug Administration in 1984. Since Dornier's pioneering work, numerous other companies have demonstrated that shock waves capable of stone fragmentation may be generated by electromagnetic induction, microexplosions, focused lasers, and piezoelectric crystals. To date, more than 3000 lithotripters of all types have been placed worldwide, and more than 1 million patients are treated annually with SWL.

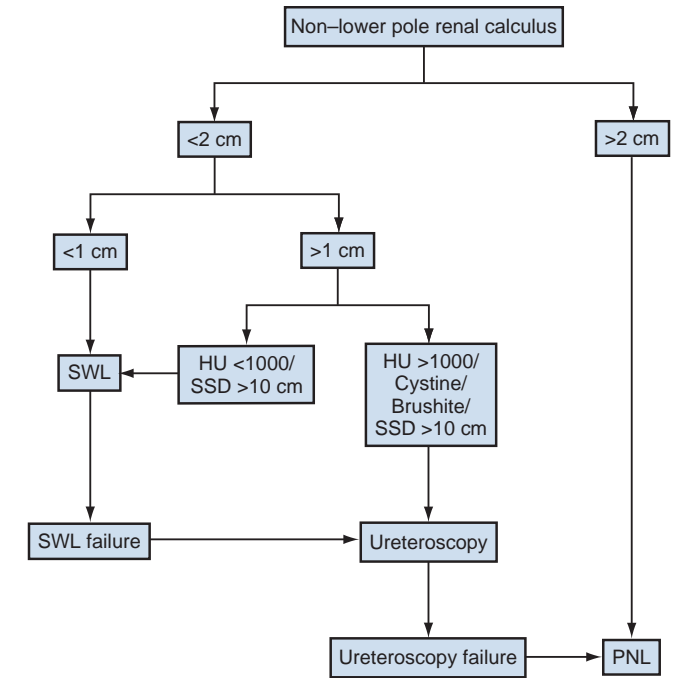

Figure 53-1. Treatment algorithm. HU, Hounsfield unit; PNL, percutaneous nephrolithotomy; SSD, skin-to-stone distance; SWL, shock wave lithotripsy. (Modified from Wen CC, Nakada SI. Treatment selection and outcomes: renal calculi. *Urol Clin North Am* 2007;34[3]: 409–19.)

BOX 53-1 Factors Affecting Management of Renal Stones	
STONE-RELATED FACTORS	CLINICAL (PATIENT) FACTORS
Size	Infection
Number	Obesity
Location	Body habitus deformity
Composition	Coagulopathy
RENAL ANATOMIC FACTORS	Juvenile
Obstruction or stasis	Elderly
Hydronephrosis	Hypertension
Ureteropelvic junction obstruction	Renal failure or transplant
Calyceal diverticulum	Solitary kidney
Horseshoe kidney	Urinary diversion
Renal ectopia or fusion	Pregnancy
Lower pole	

probability of developing symptoms from initially asymptomatic renal stones was 48.5%. [Keeley and colleagues \(2001\)](#) randomized 228 patients with asymptomatic renal stones to SWL or observation. Spontaneous passage was noted in 17% of the observation group and 28% of the SWL group ($P = .06$). There was no difference in the need for additional interventions (analgesics, antibiotics, SWL, stent insertion, URS) between the observation and SWL groups (15% vs. 21%, $P = .27$); however, invasive interventions were required only in the observation group. Despite this, there was no appreciable difference in renal function, quality of life, or stone-related symptoms between the two groups, leading the authors to conclude that SWL was not advantageous for small, asymptomatic renal stones.

[Burgher and colleagues \(2004\)](#) retrospectively reviewed 300 male patients with asymptomatic renal stones with a mean follow-up of 3.26 years. Disease progression, defined as the need for interven-

Figure 53-2. Three-dimensional computed tomography reconstructed image of a staghorn calculus.

tion, stone growth, or the development of stone-related pain, was seen in 77% of patients, with 26% of patients requiring surgery. Larger stone size and renal pelvis location were associated with disease progression. All renal pelvis stones and those larger than 15 mm experienced disease progression. The extrapolated risk of intervention at 7 years was 50%. In a similar study by [Boyce and colleagues \(2010\)](#), 20.5% of initially asymptomatic patients with renal stones became symptomatic over a 10-year period. [Koh and colleagues \(2012\)](#) found a 20% rate of spontaneous passage, 46% rate of stone progression, and 7.1% rate of intervention.

[Inci and associates \(2007\)](#) showed that approximately one third of lower pole calculi enlarge, 21% pass spontaneously, and 11% eventually require intervention. Mean stone size was 8.8 mm, and average follow-up was 52 months. No intervention was required in any patient during the first 2 years of observation. In a similar prospective, randomized study, [Yuruk and colleagues \(2010\)](#) demonstrated an 18.7% intervention rate for asymptomatic lower pole renal stones, with a median time to intervention of 22.5 months. [Kang and colleagues \(2013\)](#) reported a 29% spontaneous passage rate, 24.5% intervention rate, and 53.6% stone-related-events rate in 347 patients with mean follow-up of 31 months.

Taken together, these studies imply a number of findings about asymptomatic renal stones that can be used to advise patients as to their ideal care. First, overall stone disease progression, as defined by the development of stone-related symptoms or stone growth, occurs in as many as 50% to 80% of cases, with a calculated risk of approximately 50% at 5 years. Second, spontaneous stone passage occurs about 15% of the time and is more likely in stones 5 mm in size or smaller. Third, larger stones and those located in the renal pelvis are more likely to become symptomatic. Finally, the risk of eventual surgical intervention for initially asymptomatic renal stones is approximately 10% to 20% at 3 to 4 years after the stones are initially discovered.

Staghorn Calculi

Staghorn calculi are large renal stones that occupy most or all of the renal collecting system. The name arises from the fact that these stones look like the antlers of a deer or stag on imaging ([Fig. 53-2](#)). The stones frequently involve the renal pelvis and branch into the surrounding infundibula and calyces. No standardized definitions exist for complete and partial staghorn stones, although most

consider complete staghorn stones to occupy the entire renal collecting system, whereas partial staghorn stones occupy less. Struvite composes the majority of staghorn stones, although this configuration of collecting system involvement can include any type of stone (Segura et al, 1994). Before the era of endourology, staghorn stones were not always treated, because the surgical morbidity was high and achieving stone-free status was challenging (Segura, 1997). More recent data have improved our understanding of the natural history of staghorn stones, and the contemporary consensus is that staghorn stones should be treated. **Untreated, staghorn stones are associated with recurrent UTIs, urosepsis events, renal functional deterioration, and a higher likelihood of death (Blandy and Singh, 1976; Koga et al, 1991; Segura et al, 1994; Teichman et al, 1995).** Complete renal function loss in 50% of affected kidneys can occur after 2 years without treatment. Indeed, the American Urological Association (AUA) guideline on the management of staghorn calculi (2005) advocates for the surgical treatment of newly diagnosed struvite staghorn stones in otherwise healthy individuals, with complete stone removal as the therapeutic goal (Preminger et al, 2005).

Pretreatment Assessment

Before the surgical treatment of renal and ureteral stones, a thorough medical history and physical examination, proper imaging studies, and appropriate laboratory tests are necessary in all patients. In some instances, more elaborate laboratory analysis and upper urinary tract anatomic and functional studies may provide important additional information that is useful in surgical decision making.

Medical History

A number of medical and surgical conditions affect urinary calculi formation and have an impact on treatment planning. Medical conditions that predispose to nephrolithiasis formation should be considered in all stone formers (Strauss et al, 1982). Hyperparathyroidism, renal tubular acidosis (type 1), inflammatory bowel disease and chronic diarrhea, prior intestinal resection and gastric bypass surgery, sarcoidosis, cystinuria, metabolic syndrome and diabetes, gout, recurrent UTIs, spinal cord injury, prior urinary tract surgery, anatomic abnormalities, and medullary sponge kidney, among others, are all associated with urinary stone formation. In addition to treating symptomatic stones in these patients, medical treatment is often required for the underlying disorder and usually assists in preventing further stone formation.

An understanding of a patient's prior stone surgeries and stone composition is also important. Patients with particularly dense stones (i.e., cystine, calcium oxalate monohydrate, brushite) and obese patients are less well suited for SWL, and complete stone clearance is essential with infectious stones. Failed prior approaches may certainly suggest the need for a more invasive or comprehensive approach for the new presentation, as well as a correction of any anatomic factors that may be associated.

Certainly, all patients, and in particular those with a history of cardiovascular and cerebrovascular disease, need to be risk stratified and medically optimized before any stone therapy. Patients on anticoagulation, those with high cardiovascular risk, and those with recent coronary artery stents may need to remain on anticoagulative or antiplatelet agents perioperatively, which must be considered when selecting the best surgical approach. Consultation with the patient's cardiologist or hematologist is recommended.

Imaging

Preoperative urinary tract imaging is required in all patients before surgical intervention, to assess stone size and anatomic considerations (stone location, obstruction, stone radiologic characteristics). In the past, plain abdominal radiography and intravenous urography and tomography were routinely used; however, plain abdominal radiography (kidney-ureter-bladder [KUB] study) has

limited sensitivity and specificity, and its ability to easily demonstrate a stone is subject to multiple stone and patient anatomic factors. Approximately 10% to 20% of stones are uric acid and hence radiolucent, and roughly a third of ureteral stones occur in the mid-ureter and hence are screened by the sacroiliac bone structure. In addition, body habitus can influence film quality, as will the presence of bowel contents, which can screen a stone from view (Levine et al, 1997; Jackman et al, 2000).

More recently, noncontrast helical CT has gained widespread acceptance as the imaging modality of choice for urinary stones (Heidenreich et al, 2002). CT visualizes almost all renal stone types and has sensitivities and specificities of greater than 95%, which is considerably better than any other imaging modality, even at low dose protocols and across all body habitus (Chen et al, 1999; Hamm et al, 2001; Pfister et al, 2003; White et al, 2007; White, 2012). In addition, CT has the advantage of providing three-dimensional anatomic information about the kidney and adjacent organs, relevant treatment strategy considerations such as skin-to-stone distance, and stone density characteristics to help guide therapeutic choices (White, 2012).

Routine CT scanning may expose patients to cumulative radiation risks; accordingly, modern low-dose imaging protocols are widely used to adhere to the ALARA ("as low as reasonably achievable") principle and thus reduce the radiation exposure while retaining sufficient anatomic and stone details (Lipkin and Preminger, 2013). Only on occasion are more detailed anatomic and functional studies necessary, such as contrast-enhanced studies or renal scintigraphy.

Renal ultrasound has become a more widely used modality for initial evaluation in recent years. Greater experience in its use among both urologists and emergency medicine physicians has led to its greater availability as a screening tool to determine whether a CT scan is necessary (Dalziel and Noble, 2013). Kocher and colleagues reported that use of CT for suspected renal colic had increased from 4% to 42% between 1996 and 2007, although there was no overall increase in stone diagnosis or hospital admissions during the same period of time (Kocher et al, 2011). Recognition of this overuse of CT scanning has led to the implementation of urinalysis- and renal ultrasound-based algorithms to try to decrease it (Edmonds et al, 2010; Riddell et al, 2014).

Chronic kidney stone formers can also be monitored over time with serial ultrasound examinations as a means to reduce radiation exposure to these patients. The limitations of renal ultrasound include the inability to visualize most ureteral stones and a well-recognized poor correlation between measured and actual stone size and location.

More recently, high-Tesla magnetic resonance imaging (MRI) and magnetic resonance urography are being explored as possible alternatives to CT. Preliminary studies have reported sensitivities, specificities, and diagnostic accuracies of 80% or higher for renal and ureteral stones (Semins et al, 2013).

Laboratory Tests

Preoperative urinalysis and culture are mandatory before any stone surgery, and positive cultures should prompt appropriate treatment before the day of surgery. Administration of preoperative antibiotics for 1 week preceding surgery may reduce associated complications (Mariappan et al, 2006; Bag et al, 2011). Despite appropriate antibiotic therapy, sepsis is still a risk; both stone culture and renal pelvis culture are better predictors of postoperative sepsis and infectious complications than bladder urine culture results (Mariappan et al, 2005). Therefore, patients with radiographic or clinical histories suspicious for infectious or struvite stones should receive culture-directed or broad-spectrum antibiotics before surgery.

Urinalysis may reveal clues to underlying stone composition based on the presence of crystals, and urinary pH may add useful information when one is considering uric acid stones or the presence of urease-producing bacteria.

Assessment of underlying renal function is necessary, and serum creatinine often serves as an adequate evaluation, although it reflects

total function only. As stated earlier, prolonged presence of untreated staghorn stones, or a long-term, chronically obstructed kidney can significantly affect function of the affected kidney, and in patients with severe, unrecoverable compromise, nephrectomy rather than stone removal may be the most prudent treatment.

Preoperative serum chemistries are important because they may provide clues to underlying systemic diseases such as renal tubular acidosis or hyperparathyroidism or other metabolic derangements. When PCNL or laparoscopic or open stone removal is contemplated, preoperative complete blood counts should be obtained. Routine assessment of coagulation status using prothrombin time (PT) and activated partial thromboplastin time (APTT) is imperative in patients on anticoagulation therapy, but recent reviews have suggested that routine testing may not be necessary. This has been slow to be adopted in clinical practice owing to a lack of prospective, randomized controlled trials (Dzik, 2004).

Stone Factors

When treatment for any patient with a renal stone is being contemplated, the main stone-related factors include stone burden (total number and size of stones), stone location, and stone composition. Unless prior stone composition is known, absolute stone type is difficult to determine preoperatively. Certain predictions regarding stone composition can be made based on CT scan data, with increasing resistance to fragmentation associated with higher Hounsfield unit (HU) measurements. In addition to stone density, stone burden and location play important roles in the selection of the optimal surgical approach.

Treatment Decision by Stone Burden

The total kidney stone burden, or total volume of stone(s) requiring treatment, is arguably the most important factor influencing treatment decisions. Problematically, however, there is no standard for reporting kidney stone burden. Accordingly, the following decision analysis is based on the largest single-dimensional stone diameter measured on plain radiography or CT. Based on the available evidence, it is convenient to stratify stone burdens as those up to 1 cm, those between 1 cm and 2 cm, and those greater than 2 cm.

Because staghorn stones reflect additional complexity with respect to treatment owing to both the volume and the branched nature of the stone, and because there is ample literature specifically regarding staghorn stones, these are discussed separately.

Kidney Stone Burden up to 1 cm. The majority (50% to 60%) of solitary kidney stones are 1 cm or less in diameter, and many of them are asymptomatic (Cass, 1995; Renner and Rassweiler, 1999; Logarakis et al, 2000). Given enough time, however, many will enlarge or become associated with clinical factors that warrant treatment. Almost all renal stones 1 cm or smaller may be treated with SWL, URS, or PCNL. Laparoscopic or open stone removal is necessary in exceedingly rare cases, most often when there is underlying aberrant anatomy.

SWL has been considered first-line treatment for these smaller kidney stones without complicating clinical or renal anatomic considerations because it is the least invasive modality, achieves reasonably high stone-free rates, and requires the least technical skill. More recently, flexible URS use, instrumentation, and familiarity are growing within the urologic community, and in experienced hands, flexible URS should now be considered an alternative first-line therapy for kidney stone burden 1 cm or less in size. Stones with high attenuation on CT (≥ 900 HU) and those located in lower pole calyces represent special situations for which SWL clearance rates are poor. In these instances, URS or PCNL may be the preferred first-line treatment options or become necessary if SWL fails.

The European Association of Urology (EAU), in its urolithiasis guidelines, recommends SWL as the preferred first-line therapy for all kidney stones smaller than 10 mm, with URS as an alternative for selected cases and PCNL reserved for when SWL and URS have

failed (Turk et al, 2013). The AUA has not published guidelines for renal stones smaller than 10 mm.

For kidney stones 1 cm or less in diameter, SWL achieves stone-free rates of approximately 50% to 90% and effectiveness quotients of approximately 50% to 70% (Ackermann et al, 1994; Abdel-Khalek et al, 2004; Albala et al, 2005; Galvin and Pearle, 2006; Tailly et al, 2008; Micali et al, 2009). It should be recognized that most of these studies have assessed stone-free outcomes using renal ultrasound or plain radiography. Successful clearance is highest for stones in the renal pelvis and ureteropelvic junction (UPJ); 80% to 88%), favorable for stones in the upper and middle calyces (approximately 70%), and consistently less for lower pole stones (35% to 69%) (Fialkov et al, 2000; Albala et al, 2001; Pearle et al, 2005; Danuser et al, 2007). Stone-free rates with the newer second- and third-generation SWL machines have been somewhat disappointing and have yet to match those seen with Dornier HM3, which is considered the gold standard treatment in SWL. This has been the consequence of downsizing the newer generation lithotripters in an attempt to make them more portable and decrease anesthetic requirements.

Even for kidney stones smaller than 1 cm, myriad circumstances exist for which SWL is contraindicated or less effective than other modalities. Box 53-2 lists the contraindications for SWL; Box 53-3 describes clinical and renal anatomic factors that make SWL less favorable than URS or PCNL for treating kidney stones.

Over the last decade, technologic advances in flexible endoscope design and instrumentation have facilitated the use of URS, also referred to as *retrograde intrarenal surgery*, for the treatment of kidney stones. Multiple reports have now clearly established URS as a reasonable alternative for the treatment of most kidney stones, especially those smaller than 1 cm. Flexible, rather than semirigid, URS is usually necessary to access most middle and lower calyces. Compared with SWL, URS has the advantage of actively removing stones and thereby expediting stone clearance.

Contemporary URS for renal stones 1 cm or smaller offers stone-free rates of approximately 80% to 90%, with recent series reporting even better outcomes. Note that many of these reports are from high-volume stone centers. Thus, URS for small renal stones in experienced hands consistently provides stone-free rates superior to those of SWL and requires fewer ancillary procedures to do so.

BOX 53-2 Contraindications to Shock Wave Lithotripsy

- Pregnancy
- Uncorrected coagulopathy or bleeding diathesis
- Untreated urinary tract infection
- Arterial aneurysm near stone (renal or abdominal aortic aneurysms)
- Obstruction of urinary tract distal to stone
- Inability to target stone (skeletal malformation)

BOX 53-3 Factors Negatively Affecting Shock Wave Lithotripsy Success

- Stone composition (cystine, brushite, calcium oxalate monohydrate, matrix)
- Stone attenuation ≥ 1000 HU
- Skin-to-stone distance >10 cm (morbid obesity)
- Renal anatomic anomalies (horseshoe kidney, calyceal diverticulum)
- Unfavorable lower pole anatomy (narrow infundibulopelvic angler, narrow infundibulum, long lower pole calyx)

Sabnis and associates (2013) randomized 70 patients with renal stones smaller than 1.5 cm to either micro-PCNL or URS and found a 94% clearance rate for URS and 97% clearance rate for micro-PCNL. Sener and colleagues (2014) prospectively randomized patients with lower pole calculi to SWL or flexible URS and found a significantly better stone-free rate with URS (100% vs. 91.5%), whereas the SWL cohort required an average of 2.7 treatment sessions. The Global Ureteroscopy Study, which included an international, multi-institutional cohort of 11,885 patients, reported an 85.6% stone-free rate, although this study included both ureteral and renal stones (de la Rosette et al, 2014).

These excellent results contrast sharply to those from the well designed, multicenter, prospective, randomized Lower Pole II study, which reported only a 50% stone-free rate for URS of lower pole stones 1 cm or smaller (Pearle et al, 2005). This difference is believed to be secondary to the use of CT to evaluate stone-free status and the fact that this study accrued patients more than a decade ago, closing in 2003. Since that time, URS has experienced marked technologic advances, which are believed to have made URS safer and better.

The increased stone clearance of URS compared with SWL comes at the cost of a traditionally higher, albeit low, complication rate. Contemporary ureteroscopic series have shown a noticeably lower rate of complications than in prior years. In the Global Ureteroscopy Study, the overall complication rate was 3.5%, with sepsis (0.3%), ureteral stricture (0.3%), and death (0.02%) occurring rarely (de la Rosette et al, 2014). Similarly low complication rates have been reported by others, with rates of ureteral perforation, avulsion, and stricture rates all below 1%, and often below 0.5% (Butler et al, 2004; Geavlete et al, 2006). Taken together, the recent literature suggests that URS in experienced hands has an excellent safety profile, with stone-free rates and treatment efficiency superior to SWL for small renal stones.

PCNL is reserved for failures of SWL and URS or for patients with anatomic considerations making PCNL vastly superior, such as lower pole stones with acute infundibulopelvic angles or calyceal diverticula. So-called “mini” and “micro” PCNL procedures appear to offer similar stone-free rates as traditional PCNL, but with an overall lower complication rate thought to be secondary to the smaller tract dilation. Such techniques may be ideally suited for stones smaller than 1 cm that require PCNL.

Kidney Stone Burden between 1 and 2 cm. For renal stones between 1 cm and 2 cm, SWL, URS, and PCNL are the most frequently used treatments, with laparoscopic and open stone removal seldom necessary. Stone location, composition, and density and patient anatomic factors become increasingly relevant as stone burden enlarges and have an important impact on treatment outcomes. Larger stone burdens located in lower pole calyces, increasing skin-to-stone distance, and unfavorable lower renal pole anatomy all decrease the success rates of SWL and URS but have limited influence on PCNL outcomes. Thus, for renal calculi between 1 cm and 2 cm, stone-specific and anatomic factors must be carefully considered when weighing the relative outcomes and invasiveness of each procedure (see Fig. 53-1).

As a general principle, the efficacy of SWL decreases while the need for ancillary procedures and re-treatment increases as stone burden enlarges (Drach et al, 1986; Lingeman et al, 1986; El-Assmy et al, 2006; Wiesenthal et al, 2011). The same holds true for URS, although to a lesser degree. Although clearance of residual fragments has been observed up to 2 years after SWL, larger initial stone burdens are associated with larger postoperative residual fragments and higher re-treatment rates (Fig. 53-3).

For stones between 1 cm and 2 cm that are *not* located in the lower pole, SWL has traditionally been recommended as first-line therapy, and remains so in the most updated urolithiasis guidelines from the EAU (Turk et al, 2013). In general, SWL is favored when stones are not located in the lower pole, stone attenuation is less than approximately 900 HU, skin-to-stone distance is less than 10 cm, and the patient has no history of SWL-resistant minerals (cysteine, calcium oxalate monohydrate, brushite). When these factors are present, URS or PCNL should be considered

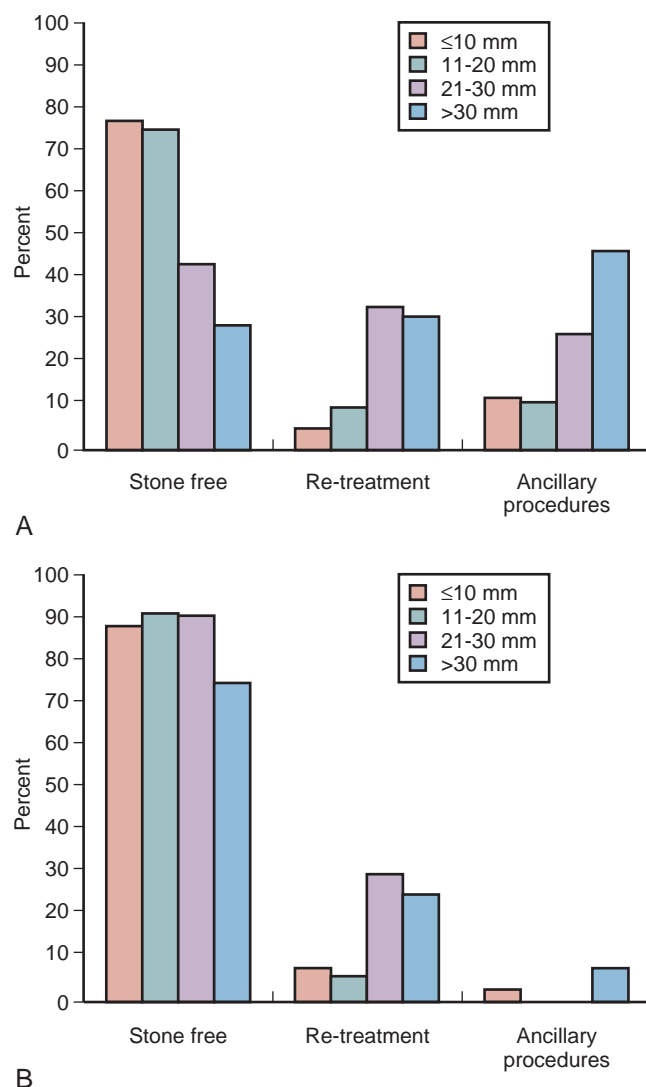

Figure 53-3. A, Solitary nonstaghorn calculi treated by shock wave lithotripsy, stratified by size. B, Solitary nonstaghorn calculi treated by percutaneous nephrolithotomy, stratified by size.

a more desirable initial treatment because SWL is more likely to fail.

Shock wave lithotripsy treatment success rates exceeding 70% have been reported for stones in the upper (71.8%) and middle (76.5%) calyces (Saw and Lingeman, 1999). Lower pole stone clearance rates range lower, between 37% and 61% (Saw and Lingeman, 1999; Albala et al, 2001; Riedler et al, 2003). Nomograms have been developed to predict SWL treatment success and reflect worse outcomes with increasing stone burden and skin-to-stone distance (Kanao et al, 2006; Wiesenthal et al, 2011). The nomogram by Kanao and colleagues (2006) predicts stone-free rates after a single SWL session of 56.8% (11 to 15 mm) and 35.1% (16 to 20 mm) for solitary calyceal stones and 64.4% (11 to 15 mm) and 42.7% (16 to 20 mm) for renal pelvis stones.

URS is a reasonable treatment approach for many kidney stones between 1 cm and 2 cm. In general, URS provides stone-free outcomes that are at least comparable, and often superior, to SWL for such renal stones. Moreover, fewer treatment sessions are usually necessary. The tradeoff, again, is a historically higher rate of complications for URS inherent in its more invasive nature. Grasso (2000) reviewed the outcomes of URS at a single, high-volume stone center and found an overall success rate of 81% after one procedure and 90% after two procedures. Single-procedure treatment success was highest for stones in upper and middle calyces

(90%) and lower for stones in the renal pelvis and lower pole calyces (approximately 80%).

URS is also useful as a salvage therapy for failed SWL, rendering 58% of these patients stone free after a single treatment session and up to 76% of patients stone free after two URS sessions (Jung et al, 2006). Unlike SWL, which becomes less effective with increasing skin-to-stone distance, similar URS results have been found in patients with normal, overweight, and obese body mass indexes (BMIs) (Caskurlu et al, 2013).

PCNL accomplishes higher stone-free rates and requires fewer auxiliary procedures than SWL or URS for renal stones between 1 cm and 2 cm. The greater invasiveness and higher rate of significant complications of PCNL limit its widespread adoption to the treatment of all renal stones larger than 1 cm. Several series have emerged comparing outcomes among SWL, URS, and PCNL for kidney stones 1 to 2 cm in size (Resorlu et al, 2013; Bas et al, 2014). Success rates were highest for PCNL (91% to 98%), quite respectable for URS (87% to 91%), and significantly lower for SWL (66% to 86%). As expected, the PCNL groups experienced more overall and serious complications, but they also had the lowest need for additional procedures. The difference in treatment success is even more apparent when comparing SWL (37%) with PCNL (95%) for lower pole stones as demonstrated in the prospective, randomized Lower Pole I study (Albala et al, 2001).

In the last few years, smaller PCNL access sheaths have been used in an attempt to reduce PCNL-related morbidity, and out of this experience have come the terms “mini-perc” and “micro-perc.” No precise definitions have been coined, but mini-perc in general refers to PCNL performed through sheaths from 12 Fr to 20 Fr, whereas micro-perc is performed through a 16-gauge needle (Helal et al, 1997; Sabnis et al, 2012).

A few prospective reports with small sample sizes have surfaced evaluating mini-perc and micro-perc (Mishra et al, 2011; Sabnis et al, 2012, 2013). In general, mini-perc has showed equivalent stone clearance to standard PCNL (96% vs. 100%) with a smaller hemoglobin drop, shorter hospital stay, and decreased analgesic requirement. Mini-perc and URS were also found to be essentially the same in terms of stone clearance (100% vs. 97%), whereas URS was associated with a lower hemoglobin drop and less analgesic medication. Similarly, micro-perc and URS showed similar stone clearance (97% vs. 94%) and essentially equivalent blood loss, postoperative pain, and length of stay. Notably, mini-perc and micro-perc techniques are mainly performed in highly specialized, high-volume stone centers. These procedures are of significant interest, although the techniques have not yet been widely adopted by the urologic community at large. Certainly, additional studies with larger sample sizes are necessary to better evaluate these techniques and their learning curves.

Kidney Stone Burden Greater than 2 cm. PCNL should be considered first-line therapy for kidney stone burdens 2 cm and greater. Unlike URS and SWL, the success of PCNL is relatively independent of stone location and stone composition. Stone clearance was once considered independent of stone burden as well, although more recent studies suggest that stone-free rates decrease as stone burdens increase (Lingeman et al, 1987; Desai et al, 2011). Nonetheless, modern-day PCNL is the most efficient means to remove stone burdens 2 cm and greater in a single surgical setting. It is also routinely associated with shorter operative times and a lower likelihood of requiring a staged procedure, which is usually the norm when URS, SWL, or both are used to tackle larger stones. Meanwhile, the complication and re-treatment rates rise noticeably when SWL monotherapy is used to approach these larger stones.

As the most efficient means to remove large stones from the kidney, PCNL has consistently achieved stone clearance rates of at least 75%, and often much higher, when used by many different groups across the world (Segura et al, 1985; Albala, 2001; Osman et al, 2005a; de la Rosette et al, 2011). Clearance of lower pole stones is also excellent with PCNL, with a rate that has been reported as high as 95% in the Lower Pole I study (Albala et al, 2001). The superior stone-free rates come as a tradeoff for more frequent and more serious complications after PCNL compared with either URS

or SWL. Overall complication rates between 20% and 30% have been reported, with most contemporary series showing rates of transfusion of 5% to 10%, severe sepsis of 1% or less, and delayed bleeding requiring angioembolization of 1% or less (Michel et al, 2007; de la Rosette et al, 2011). Stone-free rates can be improved and blood loss decreased when flexible nephroscopy is used to augment standard PCNL (Gucuk et al, 2013).

Early after its introduction, SWL was recognized as a suboptimal modality to efficiently clear renal stones 2 cm or greater, as was reported at a National Institutes of Health (NIH) consensus conference (Consensus conference, 1988). Subsequent studies confirmed overall success rates below 30% for stones 3 cm and greater treated with SWL monotherapy (Murray et al, 1995). More recently, stone-free rates of 59% were demonstrated after SWL monotherapy for larger renal stones; however, steinstrasse (23%) and the need for secondary procedures (20%) occurred frequently (El-Assmy et al, 2006). The previously described SWL nomograms predict a stone clearance of 30% or less for renal stones 2 cm or greater (Kanao et al, 2006). When SWL is combined with URS under a single anesthesia, stone clearance rates of nearly 77% can be achieved, but require multiple stages (Hafron et al, 2005).

In the late 1990s, URS surfaced as a viable, low-morbidity alternative to SWL for large renal stones. One of the first series was reported by Grasso and colleagues (1998), with a stone-free rate of 76% after a single URS procedure and improving to 91% after a second stage. Unfortunately, at 6 months of follow-up only 60% of patients were completely clear of stones. Since this report, however, many others have followed, which describe similarly encouraging outcomes, including a mean stone-free rate of 93.7% (77% to 96.7%), an average minor complication rate of 5%, an average major complication rate of 5%, and an average of 1.6 procedures to accomplish such success (Breda et al, 2008; Mariani, 2008; Breda et al, 2009; Bader et al, 2010; Aboumarzouk et al, 2012a). More recently, a few studies have directly compared PCNL with URS for stones 2 cm and larger (Akman et al, 2012a, 2012c; Bryniarski et al, 2012). Overall, stone clearance rates remain consistently higher for PCNL (91% to 96%) than for URS (71% to 93%), and URS cohorts required staged procedures 20% to 30% of the time. Thus PCNL remains the first-line treatment for kidney stone burdens 2 cm and greater, unless significant comorbidities or contraindications to PCNL are present (frailty, coagulopathy, refusal of transfusion). In such patients, though less efficient and potentially requiring multiple stages, less invasive alternatives such as URS should be considered.

Staghorn Stones. PCNL is the method of choice for treating partial and complete staghorn kidney stones, with the caveat that poorly or nonfunctioning kidneys and those associated with xanthogranulomatous pyelonephritis may be best managed with nephrectomy. Both the AUA Nephrolithiasis Guideline Panel and the EAU urolithiasis guidelines recommend PCNL as the first-line therapy for staghorn stones in most patients (Preminger et al, 2005; Turk et al, 2013). Stone-free rates are higher with PCNL (78%) than with SWL (22% to 54%) or open surgery (71%). When staghorn stones are discovered, active stone removal should be pursued unless the patient cannot safely tolerate the surgery. Observation and nonoperative management should be discouraged, because the natural history of untreated staghorn stones has shown that they may eventually cause complete loss of function in the affected kidney, can be the cause of recurrent UTIs and sepsis episodes, and are associated with an increased overall mortality (Blandy and Singh, 1976; Rous and Turner, 1977; Koga et al, 1991; Segura et al, 1994; Teichman et al, 1995; Preminger et al, 2005). PCNL has proven itself safe and effective in both the adult and pediatric populations (Kumar et al, 2011).

No standardized classification system exists for staghorn kidney stones; however, in general they are defined as branched stones that occupy much of the intrarenal collecting system. Most staghorn stones occupy the renal pelvis and extend into one or more of the surrounding calyces. Historically, staghorn stones have been described as either partial or complete, depending on how fully they occupy the intrarenal collecting system. Multiple other staghorn

classification schemes have been developed but have not been widely adopted because they are cumbersome to use and have not yet made a meaningful impact on clinical decision making (Rocco et al, 1984; Griffith and Valiquette, 1987; Ackermann et al, 1989; Di Silverio et al, 1990; Mishra et al, 2012). CT with sagittal and coronal reformatting can provide excellent anatomic and stone dimension details and is valuable in preoperative treatment planning (Nadler et al, 2004; Thiruchelvam et al, 2005).

Infectious stones, those composed of magnesium-ammonium-phosphate (or “struvite”), alone or in combination with calcium carbonate apatite, have long been considered the most frequently occurring composition of staghorn calculi, with cystine, uric acid, and calcium oxalate also exhibiting the ability to form staghorn configurations. A more recent report has challenged this understanding, describing a single-center experience with 52 complete staghorns of which 56% were metabolic in nature and 44% were infectious (Gettman and Segura, 1999; Viprakasit et al, 2011). Complete stone clearance is paramount in patients with infectious stones. Incomplete stone removal in these patients can predispose to further UTIs and rapid stone recurrence, because the urease-producing bacteria can persist within the residual stone fragments (Nemoy and Staney, 1971).

Staghorn stones are challenging to treat, frequently require multiple percutaneous access tracts and/or multiple stages, and have high treatment-related morbidity. Surgical strategy should focus on selecting the procedure, or combination of procedures, most likely to render the patient stone free while minimizing morbidity. For most patients, SWL monotherapy should be avoided because it is highly unlikely to be successful and frequently is complicated by steinstrasse. In the only prospective, randomized trial comparing SWL with PCNL for staghorn stones, PCNL provided superior stone-free rates (74% vs. 22%), shorter overall treatment duration, and fewer septic complications (Meretyk et al, 1997).

Combination therapy with multiple endourologic modalities has been used as an alternative to PCNL monotherapy. In one such approach, referred to as sandwich therapy and popularized in the 1990s, staghorn stones were treated first with PCNL, then with SWL for residual or inaccessible stones, and finally with another percutaneous procedure to clear any remaining fragments (Streem et al, 1997). However, outcomes for combination therapy were comparable to those attained with PCNL monotherapy or open nephrolithotomy (Lam et al, 1992b). Because PCNL allows rapid and effective treatment of large stone burdens, as well as efficient stone clearance rather than requiring spontaneous passage, combined approaches should be based around PCNL as the principal procedure. The use of flexible nephroscopy during PCNL can improve stone clearance and also reduce the number of access tracts necessary by allowing access to calyces unreachable with rigid instruments (Wong and Leveillee, 2002). Retrograde flexible URS can be of similar benefit (Marguet et al, 2005).

URS as the sole modality to treat complete staghorn stones is highly unlikely to be successful and has not been reported. URS may be considered an alternative to PCNL for simple partial staghorn stones in patients with favorable anatomy or with contraindications to PCNL, although it often requires multiple stages (Cohen et al, 2013).

Laparoscopic and robotic-assisted techniques have been described in small series for the treatment of complete, or nearly complete, staghorn stones (Giedelman et al, 2012; King et al, 2014). Although these techniques have been shown to be feasible, actual stone-free rates were relatively low (29% to 67%) and the techniques provide no obvious advantage over PCNL for routine staghorn stones in anatomically straightforward situations. In extenuating circumstances, such as ectopic kidneys, laparoscopic or robotic assistance may prove helpful in allowing safe access into the collecting system.

Open nephrolithotomy, once the preferred approach to staghorn stones, is now reserved for rare instances where complicating factors make PCNL impossible or unlikely to achieve reasonable stone clearance within an acceptable number or combination of procedures. Stone-free rates for open surgery have been reported to be as

high as 85%; however, since the rise of endourology and PCNL, superior stone-free rates are routinely achievable with PCNL (Lingeman et al, 1987; Al-Kohlany et al, 2005). In addition, length of hospital stay, the risks for blood transfusions and of renal function loss, and postoperative pain and convalescence all favor PCNL over open nephrolithotomy.

Treatment Decision by Stone Localization

Although total stone burden is arguably the most important consideration when deciding how to approach a given patient's stone disease, the location and distribution of stones within the kidney are often the next most important considerations; this is particularly true for stones between 1 cm and 2 cm in size. The location of stones within the kidney can be simplified to two groups: lower pole stones and non-lower pole stones. Lower pole stones tend to prove the most difficult to treat, especially when the lower pole anatomy is unfavorable (acute infundibulopelvic angle, long infundibular length, narrow infundibular width), because it becomes challenging to reach this location ureteroscopically or to ensure stone clearance with SWL. Because stones within the lower pole are dependently positioned, they are less likely to pass spontaneously after fragmentation by SWL or URS without adjunctive positioning or the use of percussion techniques to assist passage. In addition, the unfavorable anatomic factors may limit passage of fragments even with those adjunctive treatments.

Many studies have evaluated the impact of lower pole stone location on treatment success and complications for a variety of stone treatment modalities. Further discussion of lower pole stones and the influence of lower pole anatomy on treatment outcomes is covered in the section on lower pole calculi. Suffice it to say, **stones situated in the lower pole prove more difficult to clear with URS or SWL, and therefore stones 1 cm or larger within the lower pole may be most efficiently treated with PCNL.** Stones in a non-lower pole location tend to respond more readily to SWL and URS, making those techniques more competitive with PCNL.

For non-lower pole renal stones treated with SWL, firm conclusions about treatment outcomes based on differences in non-lower pole renal stone location are difficult to make because the available studies use a variety of different lithotripters and include nonuniform stone burdens and wide variation in both the assessment and definition of successful stone clearance. Nevertheless, some patterns emerge when the available data are pooled (Graff et al, 1988; Kosar et al, 1998; Coz et al, 2000; Obek et al, 2001; Egilmez et al, 2007; Turna et al, 2007; Seitz et al, 2008; Khalil, 2012; Neisius et al, 2013). In general, **non-lower pole kidney stone treatment success by SWL tends to be similar for any given stone size regardless of the precise intrarenal location.** That is, stone clearance rates and effectiveness quotients are reported as statistically similar for stones in the renal pelvis, upper pole calyces, and middle calyces within a given study, despite differences in absolute numbers among studies. Thus, stone size and composition, rather than stone location, should dictate SWL treatment decisions.

Few recent studies have evaluated URS outcomes based on stone location. With the vast advancements in endourology over the past decade, flexible ureteroscopes can often access all locations within the intrarenal collecting system.

Before the newer-generation flexible ureteroscopes with improved deflection capabilities, lower pole calculi often proved more challenging to access and completely clear. With modern flexible ureteroscopes, however, lower pole stones can be reached in most instances, and small or partially fragmented stones can often be repositioned into more favorable intrarenal locations (e.g., renal pelvis or upper pole). **Excellent stone clearance with URS has been reported for all renal stone locations (>80% to 90%), suggesting that stone size and density, along with patient anatomy, are more important factors than intrarenal stone location when considering URS treatment decisions** (Portis et al, 2006; Perlmutter et al, 2008; Hussain et al, 2011).

Similar to URS, data are sparse with regard to PCNL outcomes based on specific stone location. With the addition of flexible

nephroscopy at the time of initial PCNL, much of the kidney and hence stones in many intrarenal locations are accessible through the initial percutaneous tract. There is, however, **some evidence to suggest that upper pole calyceal stone location in patients undergoing PCNL is an independent predictor of incomplete stone clearance**, although this study concentrated on single-tract PCNL only (Shahrour et al, 2012). In developing a nomogram to predict stone-free status after PCNL, Smith and colleagues found that stones within the middle calyx and renal pelvis were more likely to be cleared than stones in an upper or lower calyceal location (Smith et al, 2013). It is interesting to note that, other than for staghorn stones, upper calyx location was associated with the lowest stone clearance, inferior even to stones within the lower pole.

Results from the PCNL global study demonstrated a higher rate of postoperative complications for large calyceal stones compared with large renal pelvis stones. However, those in the large calyceal stone group had more overall comorbidities and higher American Society of Anesthesiologist scores, which may be significant confounding variables (Xue et al, 2012).

Anterior versus posterior calyceal stone location may also affect PCNL outcomes. When targeting directly into the stone-bearing calyx, anteriorly located calyces require longer tract lengths and traverse more renal parenchyma than posteriorly located calyces. Tepeler and colleagues explored this hypothesis in a series in which patients were divided and found no difference in overall success and complication rates, but did note a trend toward increased severe hemorrhagic events in the cohort with anterior calyceal stones (Tepeler et al, 2013).

Treatment by Stone Composition

Stone composition has significant implications with respect to treatment outcomes primarily with SWL, whereas URS, PCNL, and laparoscopic and open stone surgery appear to be only minimally affected. When composition is known, a prior stone analysis can be used to better decide on therapy.

In general, cystine, calcium phosphate (specifically “brushite”), and calcium oxalate monohydrate stones are the most resistant to SWL. The remainder of the common stone types by order of increasing fragility are struvite, calcium oxalate dihydrate, and finally uric acid stones (Pittomvils et al, 1994; Zhong and Preminger, 1994; Saw and Lingeman, 1999).

Zhong and Preminger (1994) showed that brushite and calcium oxalate monohydrate stones’ resistance to SWL can be explained by their inherent mechanical properties (higher Young’s modulus, greater hardness and fracture toughness). The resistance of cystine stones to SWL lies in their ductile structure, which conveys a higher resilience to internal crack propagation and a higher deformation capability. In addition, SWL fragmentation of cystine, brushite, and calcium oxalate monohydrate results in relatively larger stone fragments than other stone compositions, which may negatively affect subsequent stone clearance (Dretler, 1988; Pittomvils et al, 1994; Rutchik and Resnick, 1998).

In vitro studies have shown that holmium laser lithotripsy fragmentation efficiency is also dependent on stone composition, with the poorest fragmentation seen for calcium oxalate monohydrate stones and moderate fragmentation seen for uric acid and cystine stones (Teichman et al, 1998a). However, this may have little clinical practicality, as a separate study by Teichman and associates (1998b) demonstrated that holmium laser lithotripsy was able to successfully fragment all stone types tested and resulted in no fragments larger than 4 mm (Teichman et al, 1998b). Moreover, when stone basket extraction was added to holmium laser lithotripsy, Wiener and colleagues showed that operative time was independent of stone composition (Wiener et al, 2012).

Stone attenuation values (in Hounsfield units) on CT have been correlated to stone composition, although overlap exists across many stone types. Numerous investigators have shown that uric acid stones consistently have lower Hounsfield unit values than calcium oxalate monohydrate stones and can be readily discerned from them on helical CT (Mitcheson et al, 1983; Mostafavi

et al, 1998; Nakada et al, 2000; Kulkarni et al, 2013; Marchini et al, 2013). Moreover, uric acid stones tend to display more homogeneous attenuation throughout a given stone than calcium oxalate stones (Marchini et al, 2013). Discriminating between struvite- and calcium-containing stones is usually not possible based on stone attenuation alone, as considerable overlap exists between them.

Even though stone attenuation values are far from perfect in accurately determining stone composition, stone attenuation can be helpful in predicting treatment success with SWL. Multiple studies now show that attenuation values higher than 900 to 1000 HU are associated with poorer outcomes with SWL (Joseph et al, 2002; Gupta et al, 2005; Wang et al, 2005; El-Nahas et al, 2007). Indeed, Gupta and colleagues (2005) have shown a linear relationship between SWL fragmentation success and stone attenuation, with decreasing fragmentation as stone attenuation increases. Joseph and colleagues (2002) reported that stone clearance with SWL occurred in just 54.5% of patients with stone attenuation levels above 1000 HU, whereas success was seen in 85.7% of patients when stone attenuation was between 500 and 1000 HU and in all patients with stone attenuation below 500 HU. Ouzaid and associates (2012) showed that a threshold of 970 HU was the most sensitive and specific cutoff value to predict treatment success with SWL. Stones below 970 HU were associated with an SWL treatment success rate of 96%, whereas stones above 970 HU were successfully treated only 38% of the time. Similar to the study by Gupta and coworkers (2005), this study found a linear association between SWL success and stone attenuation.

Matrix. Matrix renal stones are rare, and unlike most other renal stones in that they are predominantly (approximately 65%, range 42% to 84%) composed of organic proteins, sugars, and glucosamines, whereas other crystalline calculi have only minimal organic material (2.5%) (Boyce and King, 1959). In addition, these stones are soft, gelatinous, and relatively amorphous (Fig. 53-4). Matrix stones can be challenging to diagnose preoperatively, as they can mimic upper tract collecting system soft-tissue masses and require a high index of suspicion. Traditionally described as radiolucent, these stones often exhibit either a radiodense calcific center or faint peripheral rim of radiodensity, and both of these signs are frequently visible on preoperative imaging (Fig. 53-5) (Bani-Hani et al, 2005; Shah et al, 2009). These stones tend to be large and can assume partial staghorn configurations, and therefore PCNL is the preferred treatment approach for most matrix renal stones owing to its high success rates and low recurrence rates. It should be noted that descriptions of successful treatment with URS have been reported (Stoller et al, 1994b; Rowley et al, 2008; Shah et al, 2009; Chan et al, 2010), but SWL is ineffective in these stones, given their soft composition and relative paucity of brittle mineral content.

Please see the Expert Consult website for additional details related to treatment by stone composition.

Renal Anatomic Factors

Ureteral Pelvic Junction Obstruction

Ureteropelvic junction obstruction (UPJO) is associated with kidney stones up to 20% to 30% of the time (Rutchik and Resnick, 1998; Berkman et al, 2009). Before undertaking any surgical correction, it is vitally important to try to distinguish if the UPJO is the underlying disorder with subsequent renal stone formation, or if a renal pelvis or UPJ stone provoked edema at the UPJ, giving the misleading appearance of UPJO when none actually exists. Although this is not always straightforward, review of CT cross-sectional imaging can provide some insights. For example, when smaller stones are found in calyceal locations with a significantly hydronephrotic renal pelvis and tight UPJ or proximal ureter, UPJO is likely the primary pathology with resulting stone formation. On the contrary, a stone lodged at the UPJ or a renal pelvis stone in close proximity to the UPJ may be the primary pathology causing the obstruction, with no UPJO actually existing.

If there is any question about primary UPJO or a mimic from a UPJ or renal pelvis stone, then the kidney stones should be treated and no specific therapy should be directed at the UPJ. Rather, 4 to 6 weeks after the stone has been treated, follow-up renal imaging (sonogram, CT, or MRI) can be performed to ascertain if hydronephrosis persists, and if so, further renal functional imaging may be indicated (diuretic renogram). Alternatively, if a nephrostomy tube is in place and the presence of UPJO remains equivocal, then a Whitaker test can be performed. If UPJO is confirmed at that time, only then is UPJ repair recommended.

Similarly, it is important to determine the overall renal function of the affected kidney if it appears atrophic or with thinned parenchyma. If a nonfunctioning or poorly functioning kidney is confirmed, then the simplest option may be nephrectomy rather than simply treating the stone. It is also important to determine if the UPJ has been operated on in the past. Reports have shown that UPJO that recurs after previous endopyelotomy responds favorably to minimally invasive or open pyeloplasty and that UPJO that recurs after previous pyeloplasty responds well to endopyelotomy (Canes et al, 2008; Patel et al, 2011).

A variety of strategies can be used to treat UPJO with concomitant kidney stones, with the ultimate goal of repairing the UPJO and restoring normal renal drainage while simultaneously rendering the patient stone free. PCNL with antegrade endopyelotomy, laparoscopic or robotic pyeloplasty with pyelolithotomy or neph-

rolithotomy, and retrograde endopyelotomy with URS stone removal have all been described. Endopyelotomy should be discouraged when long strictures (>2 cm) are encountered or prior endopyelotomy has been performed and failed.

As a general rule, it is prudent to clear the stone burden before incising the UPJO during endopyelotomy and before completing the UPJ repair with pyeloplasty. This is particularly important for PCNL with antegrade endopyelotomy, so that stone fragments do not extrude or settle near the area of the UPJ incision. Stone incorporated in or near the endopyelotomy site can lead to restricting through granuloma and fibrosis formation (Giddens et al, 2000). Retrograde endopyelotomy with URS stone treatment is also susceptible to this problem, as endopyelotomy is necessary as an initial step to allow the ureterorenoscope access to the kidney, and any subsequent attempts at stone fragmentation or retrieval may result in residual fragments lodging in close proximity to the UPJ.

Over the last decade an increasing number of reports have surfaced describing laparoscopic and robotic pyeloplasty with simultaneous kidney stone removal, and when combined with the available literature on minimally invasive UPJO repair, a number of patterns emerge. There appears to be no difference in operative outcomes, success, or complications of UPJO repair between laparoscopic and robotic pyeloplasty (Braga et al, 2009). Short-term success for laparoscopic and robotic pyeloplasty is excellent at over 90% and appears superior to that of antegrade endopyelotomy, which is closer to 70% to 80% (Knudsen et al, 2004; Rassweiler et al, 2007; Berkman et al, 2009). Berkman and colleagues (2009) found PCNL at the time of percutaneous antegrade endopyelotomy to have no effect on success rates of relieving obstruction. Long-term outcomes with endopyelotomy or pyeloplasty are worse than short-term results, with recurrence seen in 25% of pyeloplasties and approximately 60% of endopyelotomies after 10 years (DiMarco et al, 2006).

Laparoscopic, and more recently robotic, pyeloplasty with concurrent renal calculi removal through a pyelolithotomy achieves a stone-free rate of 75% to 100%, and with a pyeloplasty a success rate exceeding 90% (Ramakumar et al, 2002; Atug et al, 2005; Mufarrij et al, 2008; Srivastava et al, 2008; Stein et al, 2008; Stravodimos et al, 2014). Laparoscopic graspers, flexible nephroscopes and wire baskets passed through laparoscopic or robotic trocars, laparoscopic irrigation, and robotic graspers have all been used to remove renal stones through the pyelotomy incision. Operative times are approximately 3.5 to 4 hours. In one small series, combined robotic nephrolithotomy and UPJO repair was undertaken and the use of intraoperative ultrasound aided in stone identification within the kidney to direct small nephrolithotomy incisions (Ghani et al, 2014).

In very select cases in which patients have larger, highly complex stone burdens and calyceal anatomy unlikely to permit adequate stone clearance through the standard pyeloplasty incisions, performing standard PCNL first and then performing laparoscopic pyeloplasty under the same anesthetic has been described with encouraging results (Agarwal et al, 2008). However, this approach is associated with longer operative time of almost 4 hours. All patients were stone free by renal sonography at 6 months and demonstrated adequate renal drainage on renogram.

Calyceal Diverticula

Calyceal diverticula are urothelium-lined, nonsecretory, cystic dilations of the intrarenal collecting system that are thought to arise embryonically. They were first described by Rayer in 1841 and were first given the name *calyceal diverticula* in 1941 by Prather (Rayer, 1841; Prather, 1941). They have a narrow connection to the normal pelvicalyceal system, which is thought to allow for preferential urine filling and poor urine drainage from the diverticulum. Calyceal diverticula are rare, with a reported incidence of 0.2% to 0.6% in patients undergoing intravenous urography (IVU) (Middleton and Pfister, 1974; Timmons et al, 1975; Wulfsohn, 1980; Michel et al, 1985). They may arise from any portion of the pelvicalyceal system, with (approximately) 50% or more originating from the upper pole calyces, 30% from the middle pole calyces or renal pelvis, and 20%

Stone composition has the largest impact on SWL results, whereas URS, PCNL, and laparoscopic and open stone surgery are less affected by stone composition, if at all. Therefore, factoring stone composition into treatment decision analysis is most relevant for stones 2 cm or less in size, for which SWL is often considered first-line therapy or as a first-line therapeutic option. In general, cystine, calcium phosphate (specifically “brushite”), and calcium oxalate monohydrate stones are the most resistant to SWL. When patients are known to harbor such stones, in particular when combined with lower pole stone location, long skin-to-stone distances, or increasing stone burdens above 1 cm, SWL success rates decrease substantially. In such patients, recognition of this limitation should prompt consideration of another modality (e.g., URS or PCNL).

In 1988, Dretler introduced the concept of stone fragility, describing it as “the ease with which a stone fragments during SWL.” He demonstrated in vitro that calculi of various compositions fragment differently under a given set of SWL parameters (Dretler, 1988). Thereafter, additional investigations revealed that cystine, brushite, and calcium oxalate monohydrate stones were the most refractory to SWL fragmentation, with cystine and brushite being most resistant. The remainder of the common stone types by order of increasing fragility are struvite, calcium oxalate dihydrate, and finally uric acid stones (Pittomvils et al, 1994; Zhong and Preminger, 1994; Saw and Lingeman, 1999).

Zhong and Preminger (1994) showed that brushite and calcium oxalate monohydrate stones’ resistance to SWL can be explained by their inherent mechanical properties (higher Young’s modulus, greater hardness and fracture toughness). The resistance of cystine stones to SWL lies in their ductile structure, which conveys a higher resilience to internal crack propagation and a higher deformation capability. In addition, SWL fragmentation of cystine, brushite, and calcium oxalate monohydrate results in relatively larger stone fragments than other stone compositions, which may negatively affect subsequent stone clearance (Dretler, 1988; Pittomvils et al, 1994; Rutchik and Resnick, 1998). Williams and associates evaluated the number of shock waves necessary to completely fragment stones of different compositions and demonstrated a considerably higher mean number of shocks necessary for cystine (5937 shocks) and brushite (1681 shocks) stones compared with other stone types, with uric acid stones (400 shocks) requiring the least (Williams et al, 2003).

The internal structure of a stone, not just its composition, influences stone fragility, and it has been demonstrated that stones of a given mineral type can exhibit a wide range of fragility (Williams et al, 2003). This is particularly relevant for cystine stones, wherein the prevailing belief is that these stones are all resistant to SWL. In actuality, early work by Bhatta and associates showed that cystine calculi come in two predominant substructures: those with a rough external surface and those that are smooth (Bhatta et al, 1989). The rough cystine stones had well-formed, repeating internal hexagonal crystals, whereas the smooth cystine stones had irregular crystals that did not interlace well. Kim and associates took this one step further, showing that cystine stones with mixed internal low- and high-attenuation regions on CT were more readily fragmented by SWL than those with a homogeneous appearance (Kim et al, 2007). In fact, the homogeneous cystine stones required approximately 60% more shocks for comminution. This same phenomenon has been seen in calcium oxalate monohydrate stones as well with more homogeneous stones relatively more resistant to SWL than those with a heterogeneous appearance on CT (Fig. 53-6) (Zarse et al, 2007). Viewing the CT scan with bone windows can facilitate the identification of the internal structure of renal stones (Williams et al, 2002).

In vitro studies have shown that holmium laser lithotripsy fragmentation efficiency is also dependent on stone composition, with the poorest fragmentation seen for calcium oxalate monohydrate stones and moderate fragmentation seen for uric acid and cystine stones (Teichman et al, 1998a). However, this may have little clinical practicality, as a separate study by Teichman and associates (1998b) demonstrated that holmium laser lithotripsy was able to successfully fragment all stone types tested and resulted in no fragments larger than 4 mm (Teichman et al, 1998b). Moreover, when stone basket extraction was added to holmium laser lithotripsy, Wiener and colleagues (2012) showed that operative time was independent of stone composition. This study included cystine, calcium oxalate monohydrate, brushite, and uric acid stone types, among others (Wiener et al, 2012).

Unfortunately for the vast majority of patients requiring surgical treatment for kidney stones, the stone composition is unknown before surgery, and treatment decisions must be made according to information available preoperatively. Considerable information may be gleaned from preoperative imaging that can inform treatment decisions. Details about stone size, shape, and density are

Figure 53-6. Photographic and helical computed tomography images show structural variability in stones of the same type. Note that although all stones depicted are calcium oxalate in type, some have a mottled structure and others have a lamellar structure.

readily obtainable from modern CT imaging software, and noncontrast helical CT is both the most sensitive and the most widely used initial imaging study in the evaluation of suspected urolithiasis. Anatomic detail and skin-to-stone distance can also be easily determined on axial CT slices. **The combination of anatomic and stone characteristics becomes most important when deciding if a given stone is amenable to SWL or if another treatment modality should be chosen.**

Before the widespread use of CT, the imaging nuances of plain radiography were used in an attempt to predict stone fragility by SWL. Uric acid stones are radiolucent on plain radiography but readily visible on CT and respond well to SWL if they can be appropriately targeted. Stones with irregular contour and reticulated, spiculated structure tended to fragment more easily than stones with homogeneous architecture and smooth edges (Dretler, 1988; Dretler and Polykoff, 1996). Assessments of relative stone radiodensity suggested that stones more dense than nearby bony structures (transverse process or 12th rib) were more resistant to SWL than less dense stones. In addition, cystine stones have been noted to appear as ground glass on plain radiography, and when this is seen preoperatively, treatments other than SWL should be sought.

Stone attenuation values (in HU) on CT have been correlated to stone composition, although overlap exists across many stone types. Numerous investigators have shown that **uric acid stones consistently have lower Hounsfield unit values than calcium oxalate monohydrate stones and can be readily discerned from them on helical CT** (Mitcheson et al, 1983; Mostafavi et al, 1998; Nakada et al, 2000; Kulkarni et al, 2013; Marchini et al, 2013). Moreover, uric acid stones tend to display more homogeneous attenuation throughout a given stone than calcium oxalate stones (Marchini et al, 2013). Discriminating between struvite- and calcium-containing stones is usually not possible based on stone attenuation alone, because considerable overlap exists between them.

Differentiation among the various calcium-containing stones remains difficult, but in vitro evaluation using dual-source CT has shown promise in distinguishing between calcium oxalate and calcium phosphate stones (Matlaga et al, 2008; Boll et al, 2009). More recently, single-source dual-energy CT has been shown to accurately predict stone composition in stone formers with uric acid stones (6 patients), cystine stones (1 patient), and 79% of patients with calcium stones (15 of 19 patients) (Hidas et al, 2010). In the same study, the sole patient with a struvite stone was incorrectly predicted.

Even though stone attenuation values are far from perfect in accurately determining stone composition, stone attenuation can be helpful in predicting treatment success with SWL. **Multiple studies now show that attenuation values higher than 900 to 1000 HU are associated with poorer outcomes with SWL** (Joseph et al, 2002; Gupta et al, 2005; Wang et al, 2005; El-Nahas et al, 2007). Indeed, Gupta and colleagues (2005) have shown a linear relationship between SWL fragmentation success and stone attenuation, with decreasing fragmentation as stone attenuation increases. Joseph and colleagues (2002) reported that stone clearance with SWL occurred in just 54.5% of patients with stone attenuation levels exceeding 1000 HU, whereas success was seen in 85.7% of patients when stone attenuation was between 500 and 1000 HU and in all patients with stone attenuation below 500 HU. Ouzaid and associates (2012) showed a threshold of 970 HU to be the most sensitive and specific cutoff value to predict treatment success with SWL. Stones below 970 HU were associated with an SWL treatment success rate of 96%, whereas stones above 970 HU were successfully treated only 38% of the time. Similar to the study by Gupta and coworkers (2005), this study found a linear association between SWL success and stone attenuation.

Cystine. As previously described, cystine stones prove more resistant to SWL than other stone types based on their inherent chemical structure, which gives them a ductile nature, or ability to deform instead of crack, rather than any underlying hardness or density. The natural history for most cystinuric patients is recurrent stone formation over their lifetime, and although medical management

can prove useful in prevention, compliance with it is difficult and overall poor (Pietrow et al, 2003; Ahmed et al, 2008). Recurrence rates as high as 73% are seen at 5 years, and patients with residual fragments undergo more frequent re-treatments than those rendered stone free (Knoll et al, 1988; Chow and Streem, 1998). Furthermore, cystinurics have relatively worse renal function compared with calcium oxalate stone formers, and the greatest decline in renal function is found in those cystinurics who have required more stone surgeries (Barbey et al, 2000; Assimos et al, 2002). The goal, then, is to minimize surgery in these patients and, when possible, treat them in a minimally invasive manner.

Of the currently available treatment modalities, URS should assume a prominent role in the surgical management of cystinurics. Although PCNL may be necessary to treat excessively large stone burdens or complete staghorn stones, repeated PCNL, and in particular open stone removal, can contribute to renal functional decline. Therefore, URS for stone burdens in excess of 2 cm may still be the preferred surgical approach if stone clearance can be reasonably expected within one or two stages. For smaller cystine stones in non-lower pole locations and in patients with favorable anatomy (i.e., skin-to-stone distance <10 cm), SWL may be considered as a treatment option if flexible URS equipment or the technical familiarity to perform flexible URS proficiently is unavailable. However, poorer stone clearance rates than for noncystine stones should be expected, and the patient counseled appropriately.

Ureterorenoscopic management of cystine stone formers has shown favorable results with minimal morbidity (Rudnick et al, 1999; Trinchieri et al, 2007; Ahmed et al, 2008; Ruggera et al, 2011). Unfortunately, no contemporary studies using present-day flexible ureteroscopic technology have been reported, but given the limited clinical effect of stone composition on holmium laser lithotripsy, similarly excellent results should be expected for cystinurics undergoing URS. Despite this, the results of Rudnick and colleagues (1999) more than a decade ago demonstrating that encouraging treatment success (83%) with URS was achievable in cystinurics with stones up to 3 cm challenged the prevailing treatment algorithm at the time proposed by Kachel and colleagues (1991). Based on their work, Kachel and colleagues (1991) recommended that cystine stones smaller than 1.5 cm in diameter be treated with SWL and cystine stones larger than 1.5 cm in diameter be approached with PCNL. Stone-free rates with PCNL for cystine stones routinely offer stone-free rates exceeding 90%, whereas SWL outcomes are lower, with a 70.5% stone-free rate for stones smaller than 20 mm and a 41% stone-free rate for stones 20 mm or larger (Hockley et al, 1989).

Brushite. From a treatment decision perspective, brushite stones should be approached like cystine stones, and minimally invasive therapies should assume a primary role. The main reason for this is that brushite stones are relatively refractory to SWL, surpassed only by cystine stones (Dretler, 1988; Ringden and Tiselius, 2007). With contemporary URS achieving stone-free rates in excess of 90%, even for stones larger than 2 cm, URS in skilled hands should be at the top of the minimally invasive treatment options for brushite stone formers (Aboumarzouk et al, 2012a). With an average of 1.5 treatment sessions necessary, SWL monotherapy has been shown to achieve treatment success in only 65% of patients and complete stone-free status in only a meager 11% of patients (Klee et al, 1991).

A retrospective review of 82 brushite stone formers showed that stone-free status was attainable in 92% of patients with one or two procedures, with most of these being PCNL (Krambeck et al, 2010). In this analysis, recurrent stone events were seen in 38% of patients at an average of 33 months after last treatment, and all had some underlying metabolic derangement found on 24-hour urine analysis, underscoring the importance of metabolic stone evaluation and long-term management in this population. It is interesting to note that up until a decade ago, SWL appears to have been used more frequently in brushite stone formers than in calcium oxalate stone formers (Parks et al, 2004). It is unclear if this is a result of the lower fragility of brushite stones, thereby subjecting brushite stone formers to more SWL treatments per stone burden, on average.

Medication-Precipitated Stones. Renal calculi composed predominantly of a medication or one of its metabolites have been described, albeit rarely. Ephedrine and guaifenesin are both radiolucent but respond well to minimally invasive therapy such as SWL and URS (Blau, 1998; Powell et al, 1998; Assimios et al, 1999). Indinavir is a protease inhibitor used to treat patients with human immunodeficiency virus and has been shown to precipitate and form stones in 4% to 13% of patients who use this medication (Wu and Stoller, 2000). Average time between medication initiation and stone event has been reported as 21.5 weeks (Reiter et al, 1999). The stones are often small and are radiolucent on plain radiography and CT. Smaller stones pass spontaneously in more than 60% of reported cases, so a trial of nonoperative management with analge-

sics, α -blockers, and hydration is warranted (Daudon et al, 1997; Kohan et al, 1999; Reiter et al, 1999; Nadler et al, 2003). It is recommended that indinavir be temporarily discontinued as well. Indications for surgical treatment or intervention, therefore, are no different than for other stones of similar size, and all minimally invasive modalities (URS, SWL, PCNL) have been successfully applied to protease inhibitor stones.

In addition, other medications have been known to form stones, including triamterene, magnesium trisilicate, ciprofloxacin, and sulfa drugs (Matlaga et al, 2003b). Finally, drug-induced calculi can occur because of loop diuretics or increased metabolites that precipitate, such as xanthine stones induced by allopurinol (Greene et al, 1969).

stemming from the lower pole calyces (Abeshouse and Abeshouse, 1963; Waingankar et al, 2014).

Stone formation within calyceal diverticula has been reported to occur between 10% and 50% of the time (Yow and Bunts, 1955; Williams et al, 1969; Middleton and Pfister, 1974). A combination of urinary stasis and metabolic derangements is believed to underlie stone development in these structures (Burns et al, 1984; Hsu and Streem, 1998; Liatsikos et al, 2000; Matlaga et al, 2007). Hsu and Streem (1998) reported a 50% rate of metabolic abnormalities in 14 patients with stones in calyceal diverticuli. In contrast, Liatsikos and colleagues (2000) reported that only 25% of patients with calyceal diverticular stones have metabolic abnormalities, compared with 77% of patients without urinary tract anatomic anomalies.

A large percentage of calyceal diverticula are asymptomatic and require no treatment; however, **diverticular stones associated with pain, recurrent infections, hematuria, or a decline in renal function warrant treatment.** Similar to other locations in the kidney, stones within calyceal diverticula have been managed through a variety of approaches including open surgery, SWL, URS, PCNL, and laparoscopic and robotic modalities. The preferred management approach depends on both stone and diverticular anatomic characteristics. Open surgery is primarily of historic interest except in extenuating circumstances, and when undertaken, the diverticulum is marsupialized and cavity lining fulgurated.

Shock wave lithotripsy has been used to treat calyceal diverticular stones, albeit with modest results, and should not be considered first-line therapy for most symptomatic diverticular stones. Although the underlying pathogenesis is not fully understood, ablation of the calyceal diverticular lining, dilation of the diverticular neck to improve drainage, or both are considered integral to achieving stone clearance and preventing stone recurrence (Cohen and Preminger, 1997). Neither of these is accomplished with SWL. Stone-free rates for SWL are typically poor, ranging from 4% to 58% (Renner and Rassweiler, 1999; Turna et al, 2007). In one of the largest reported series involving SWL of calyceal diverticular stones, Turna and associates (2007) showed a 21% stone-free rate, although 60% of patients did experience symptom relief. Symptom-free status has been achieved in 36% to 86% of patients after SWL across a number of series, with the average closer to 60%; all studies, however, involved relatively few patients. Streem and Yost (1992) reported the highest symptom relief (86%) and stone-free rates (58%) after SWL, and these results appear to be reliant on strict patient selection criteria including stones smaller than 1.5 cm and large, patent diverticular necks on IVU. With longer follow-up averaging about 24 months (12 to 49 months), the symptom-free rate had declined to 75% and stone recurrence was witnessed in one patient. In general, with longer follow-up, symptom-free status consistently appears to diminish (Jones et al, 1991a; Streem and Yost, 1992; Turna et al, 2007).

URS is a reasonable first-line treatment approach for patients with small (<2 cm) calyceal diverticular stones arising from an upper or middle calyx, and with a diverticular neck that is short and identifiable (Grasso et al, 1995b; Waingankar et al, 2014). Diverticular stones in these locations are usually accessible via retrograde URS, whereas lower pole diverticular stones present more of a challenge owing to angulation. The holmium laser can be used to incise the narrow diverticular neck, fragment stones within, and ablate the diverticular lining. Stone-free rates of 50% to 90% are found in most series, though Auge and colleagues (2002) found a much lower symptom-free rate of 35% (Fuchs and David, 1989; Grasso et al, 1995b; Batter and Dretler, 1997; Chong et al, 2000; Auge et al, 2002; Legraverend et al, 2013). Adequate diverticular obliteration is lower with the ureteroscopic approach (approximately 20%) than with a percutaneous approach (>70%), hence the need to ensure a patent and well-draining diverticular neck.

In general, most URS failures have occurred in lower pole diverticula, although a small number have occurred in upper pole diverticula with unfavorable acute-angle offshoots of the calyceal diverticular neck. Unfortunately, the ostium to calyceal diverticulum cannot be successfully located in up to 25% of cases, and when this occurs the diverticular stones cannot be treated ureteroscopically

(Auge et al, 2002; Canales and Monga, 2003). Legraverend and associates reported a 62% stone-free rate, which increased to 84% when residual fragments less than 3 mm were included. Symptom-free rate was 93%. Overall, stone-free rates are superior to those achievable with SWL but inferior to those of PCNL. Furthermore, staged URS procedures are not uncommon in this setting.

PCNL should be considered first-line treatment for most calyceal diverticular stones. Stone-free rates (70% to 100%) and symptom-free rates (77% to 100%) are excellent for PCNL, and the percutaneous approach has the most data supporting its efficacy (Hulbert et al, 1986; Cohen and Preminger, 1997; Shalhav et al, 1998; Al-Basam et al, 2000; Monga et al, 2000; Auge et al, 2002; Kim et al, 2005; Krambeck and Lingeman, 2009). Diverticular ablation rates are also excellent (>70%) with a percutaneous approach, and the overall success rates appear durable (Shalhav et al, 1998; Monga et al, 2000). Directly puncturing into the calyceal diverticulum is preferable and allows for stone fragmentation and removal, easy fulguration of the diverticular lining, and dilation of the diverticular neck if visible and desired. Ultrasound or CT guidance can be used in selected cases when retrograde contrast instillation does not fill the calyceal diverticulum and when diverticular stones are nonradiopaque (Matlaga et al, 2006a). Posteriorly located diverticuli are particularly well suited for a percutaneous approach because there is usually minimal renal parenchyma between the diverticulum and renal capsule. Anteriorly located calyceal diverticula can also be managed with a percutaneous approach; however, it is often difficult to incise and dilate the diverticular neck secondary to unfavorable angles between the entry vector and the neck.

Laparoscopic and robotic approaches for the treatment of symptomatic stones within calyceal diverticuli have been described and are usually reserved for anteriorly located, symptomatic diverticuli with thin overlying renal parenchyma, which are otherwise not amenable to less invasive endoscopic methods (Gluckman et al, 1993; Ruckle and Segura, 1994; Harewood et al, 1996; Hoznek et al, 1998; Curran et al, 1999; Miller et al, 2002; Terai et al, 2004; Wyler et al, 2005; Akca et al, 2014). Both retroperitoneal and transperitoneal approaches have been used, with the retroperitoneal method providing easier access to posteriorly located diverticula. Outcomes are superb, with a 100% stone-free rate in those series reporting it as an outcome, approximately a 92% cavity ablation rate, and a 75% to 87% average symptom resolution rate (Waxman and Winfield, 2009; Basiri et al, 2013; Waingankar et al, 2014). The average operative time reported in these studies is approximately 180 minutes, which is longer than for the other surgical approaches. Important common considerations for this approach include the use of intraoperative ultrasound to assist with diverticulum localization, direct cavity lining ablation using electrocautery or argon beam coagulation, and suturing of the diverticular neck when required to manage wide-mouthed diverticulum.

Horseshoe Kidneys and Renal Ectopia

Horseshoe Kidneys. Horseshoe kidneys are the most common renal fusion anomaly, with a reported incidence of 1 in 400 live births (Pitts and Muecke, 1975; Evans and Resnick, 1981). It is important to recognize that there is a 15% to 20% incidence of kidney stone disease in horseshoe kidneys. Most stones are composed of calcium oxalate, with the most common locations being the renal pelvis and posterior lower pole calyces (Evans and Resnick, 1981; Tan et al, 2013). Embryonically, the abnormal medial fusion of the left and right metanephric blastemata creates an isthmus that anchors the fused kidneys at the level of the inferior mesenteric artery, leading to incomplete renal ascent and malrotation (Hohenfellner et al, 1992) (Figs. 53-7, 53-8, and 53-9).

As a result, a number of anatomically important changes are noted. The renal pelvis becomes elongated and anteriorly located, the UPJ has a high insertion into the renal pelvis and is also anteriorly situated, and the proximal ureter courses more anteriorly than usual because it must traverse over the isthmus of the horseshoe kidney. Collectively, these changes are thought to impede normal urinary drainage and to promote urinary stasis and renal stone

Figure 53-7. Antegrade nephrostogram obtained after percutaneous nephrolithotomy of a horseshoe kidney via an upper pole access. Note the subcostal nature of the access and the unique calyceal orientation inherent in a horseshoe kidney.

formation. These anatomic and functional changes have an impact on the various treatment options for renal stones, and specific horseshoe kidney anatomy, stone location, and stone size must also be considered when choosing the optimal stone treatment. The presence of impaired renal drainage or UPJO should preclude SWL

Figure 53-9. Three-dimensional computed tomographic reconstruction of horseshoe kidney with bilateral staghorn calculi. Note the medial and inferior position of the horseshoe kidney. (From Tan YK, Cha DY, Gupta M. Management of stones in abnormal situations. *Urol Clin North Am* 2013;40:79–97.)

treatment, and other modalities that can address the obstruction, such as PCNL or laparoscopic pyeloplasty, should be pursued. In general, stones smaller than 15 mm and not situated in the lower pole can be approached with SWL or URS. Stones that fail treatment with SWL or URS and stones larger than 15 mm should be considered for PCNL. Based on numerous reports, stone clearance and complications in horseshoe kidneys appear to be no different than for PCNL on orthotopic kidneys.

SWL can be considered for stones less than 1.5 cm in diameter located in the renal pelvis or nondependent upper pole and mid-pole calyces. Stone-free rates of 28% to 80% have been reported, with an average closer to 58%. Moreover, multiple treatment sessions are almost always necessary (Lampel et al, 1996; Elliott et al, 2010; Ray et al, 2011; Tan et al, 2013). On average, a higher number of shocks are necessary per treatment session, and a higher re-treatment rate is found versus similar stones in orthotopic, anatomically normal kidneys (Chaussy and Schmiedt, 1984; Drach et al, 1986; Lingeman et al, 1986).

In a series of 11 patients by Vandeursen and Baert (1992), an average of 3.8 treatment sessions per renal unit were required to achieve a 55% stone-free rate, whereas the series by Ray and colleagues (2011) showed an average of 1.7 SWL sessions for a stone-free rate of 39%. In addition, Ray and colleagues (2011) reported an abysmal 9.1% stone-free rate and 25% treatment success rate after single-session SWL at 3 months in 41 patients with horseshoe kidneys. In this series, 73% of patients required additional treatments in the form of repeat SWL, PCNL, or URS, and stone-free rate and overall success rate improved to 39.1% and 63.6%, respectively (Ray et al, 2011). The efficiency quotient was disappointing, at 10.5%. Just as SWL efficacy diminishes as stone burden increases in anatomically normal kidneys, so too it diminishes in horseshoe kidneys with increasing stone burden. Sheir and colleagues (2003) found superior stone-free rates of 79% for stones up to 15 mm, compared with 53% for stones larger than 15 mm. Kirkali and colleagues (1996) similarly found poor stone-free rates (28%) for stones larger than 10 mm.

Before SWL treatment, UPJO and poor pelvicalyceal drainage must be excluded, because these are not uncommon in horseshoe kidneys and severely curtail SWL success. The more medial and central location of the horseshoe kidney makes it more difficult to properly target calyceal and renal pelvis stones because of the

overlying vertebrae, pelvic bones, and bowel gas. Anteromedially located calyceal stones present the greatest difficulty. Positioning patients in the prone position or in the modified supine position can optimize stone targeting and is often necessary for stones situated below the pelvic brim (Jenkins and Gillenwater, 1988; Gupta and Lee, 2007). In addition, long skin-to-stone distances are frequently encountered in horseshoe kidneys, which can also hinder SWL efficacy. When SWL is chosen and skin-to-stone distances are outside of the focal zone of the lithotripter, a “blast path” technique can be used, during which the stone is targeted along the same axis but beyond F2, and relies on shock wave energy transmission past F2 to fragment the stone (Locke et al, 1990).

URS is challenging in horseshoe kidneys owing to the high ureteral insertion and tortuous course of the anteriorly displaced ureter. The need for ureteral dilation is not uncommon, and ureteral access sheaths, if able to be placed safely, can significantly expedite repeated entry to and withdrawal from the pelvicalyceal system. Flexible ureteroscopes are almost always necessary to access renal stones in a retrograde fashion, and the use of small-caliber nitinol baskets and holmium laser fibers can minimize loss of URS tip deflection. **Given the aberrant anatomy, ureteroscopy appears to be ideally limited to stone burdens 2 cm or less.** Moreover, staged procedures are common when approaching these stones ureteroscopically, and particularly so among the largest stones. Given the often compromised drainage associated with horseshoe kidneys, fragmented stones should be basket extracted rather than left in situ and left to pass spontaneously.

A number of small retrospective series report favorable surgical outcomes and low morbidity with URS for stone burdens less than 2 cm in horseshoe kidneys (Andreoni et al, 2000; Weizer et al, 2005; Symons et al, 2008). No reports focus on larger stone burdens, and none compare URS with SWL or PCNL in a direct fashion. Atis and coworkers (2013) reviewed outcomes in 20 patients with 25 stones in horseshoe kidneys. Mean stone size was 17.8 mm and stone-free rate after a single procedure was 70%. Weizer and colleagues (2005) detailed the URS outcomes in 4 patients with horseshoe kidneys and four pelvic kidneys. Mean stone size was 1.4 cm, complete stone clearance was found in 75% of patients, and 88% of patients were symptom free after the procedure. Finally, Molimard and associates (2010) reported results in 17 patients with horseshoe kidneys, 4 of whom had undergone failed previous PCNL and 8 of whom had undergone failed prior SWL. In this series, mean stone burden was 16 mm, and an average of 1.5 procedures per patient were required to achieve an 88% stone-free rate, which included residual fragments smaller than 3 mm. Thus, URS can render patients stone free more than 70% of the time when stone burdens are less than 2 cm, although a staged approach may be necessary at least half the time.

PCNL is the treatment of choice for stone burdens 2 cm and greater in horseshoe kidneys, with treatment results similar to those obtained in normal kidneys. It is also the preferred method when less invasive methods, such as SWL and URS, fail to adequately treat lesser stone burdens, or when stone density may further decrease expected successful treatment with those methods. Stone-free rates are superior to those achieved with SWL or URS. Overall, an average stone-free rate of 82% to 84% has been reported, with contemporary series describing stone-free rates of 90% or greater with the concomitant use of flexible nephroscopy (Janetschek and Kunzel, 1988; Esuvaranathan et al, 1991; Jones et al, 1991b; Al-Otaibi and Hosking, 1999; Raj et al, 2003; Shokeir et al, 2004; Gupta et al, 2009b; Elliott et al, 2010; Ozden et al, 2010).

Familiarity with the anatomy of the horseshoe kidney is key to safely performing PCNL. Percutaneous access to the horseshoe kidney is often preferentially directed at a posterior upper pole calyx, which results in an access tract situated more medially than those created in orthotopic kidneys. This is because the malrotation of the horseshoe kidney positions the renal pelvis anteriorly and angles the posterior calyces almost directly posteriorly compared with normally positioned kidneys. Percutaneous tracts through the posterior upper pole calyx provide easy access into the renal pelvis and laterally positioned calyces (Elliott et al, 2010).

However, the high insertion of the lower pole, combined with the anteromedially situated calyces, will often require a flexible nephroscope to reach all calyces in the system. In addition, the more anteriorly and centrally positioned horseshoe kidney causes the access tract to be longer, and this may necessitate use of extra-long access sheaths, nephroscopes, and instruments, especially in obese patients. A retrorenal colon may accompany horseshoe kidneys, and given the altered anatomy, preoperative CT is recommended to fully evaluate the safest percutaneous tract. Supracostal access is rarely necessary because the entire horseshoe kidney is often situated below the 12th ribs, and consequently pleural injuries are rare (Raj et al, 2003; Shokeir et al, 2004). The Clinical Research Office of the Endourological Society (CROES) PCNL study group showed that median operative time was longer and percutaneous access more likely to be unsuccessful (5% vs. 1.7%) in horseshoe kidneys than orthotopic kidneys (Osther et al, 2011).

Laparoscopic assistance is only rarely used for stone surgery on horseshoe kidneys and only a few case reports exist. In general, this adjunctive technique can be useful when particularly large renal pelvis stones exist or when concomitant UPJO exists and pyelolithotomy with or without pyeloplasty is contemplated (Stein and Desai, 2007; Symons et al, 2008; Tan et al, 2013).

Renal Ectopia. Ectopic kidneys are most commonly situated in the pelvis, with the incidence of pelvic kidneys estimated at 1 in 2200 to 1 in 3000 patients. More rarely, ectopic kidneys can be located in the abdomen, in the thoracic cavity, or in a crossed, retroperitoneal location. The approach to kidney stone treatment in these instances should be highly tailored to the specific individual, stone burden, and kidney location, along with any associated kidney drainage impediments. Similarly to horseshoe kidneys, evaluation for impaired renal drainage or UPJO is prudent before embarking down a treatment path, because pelvic kidneys are routinely malrotated and often have a high ureteral insertion or UPJO, which can further hinder stone fragment passage (Gleason et al, 1994). In the appropriate setting, SWL, URS, PCNL, and laparoscopy can all be selectively applied to achieve good stone clearance rates.

Shock wave lithotripsy achieves stone-free rates of 25% to 92%, although multiple treatment sessions are the norm (Theiss et al, 1993; Talic, 1996; Semerci et al, 1997; Gallucci et al, 2001; Sheir et al, 2003; Tunc et al, 2004). With the pelvic kidney shielded posteriorly by the bony pelvis, prone positioning is often necessary to improve shock wave delivery to the pelvic kidney stones when this technique is selected. If treatment with SWL is entertained for stones in ectopic kidneys, renal functional studies evaluating renal drainage (e.g., renography) are recommended, because the presence of impaired kidney drainage is a relative contraindication to proceeding with SWL. Ureteroscopy has also been described for pelvic and ectopic kidneys with stone-free rates of 75% after a single setting, showing that URS and SWL can achieve similar outcomes but URS is more efficient (Weizer et al, 2005). This is likely because of the active fragment removal with URS, whereas SWL requires spontaneous drainage of fragments, which can be problematic in a poorly draining ectopic kidney. Ureteral access sheaths can greatly facilitate re-entry into the ectopic kidney; however, their placement should be undertaken with caution because the associated ureters can be quite tortuous and perhaps prone to injury with sheath advancement.

Stones within pelvic kidneys present unique challenges when one is attempting to perform PCNL because clear access to the kidney is seldom encountered. Nonetheless, stone clearance rates are better for PCNL than for SWL, at least in part because of active stone extraction and the ability to perform flexible nephroscopy. Traditional posterior access is hampered by the bony pelvis, and even when it can be safely accomplished can result in debilitating femoral neuropathy (Monga et al, 1995). Patients must usually be in the supine position, and safe access into the collecting system is rarely feasible without CT or laparoscopic assistance, although it has been described ultrasonographically. Desai and Jasani (2000) report a technique exploiting transperitoneal ultrasound guidance for supine PCNL in pelvic kidneys in which the ultrasound probe is used to both target the kidney and maneuver intervening intra-abdominal contents out of the way of the proposed access tract.

(Desai, 2009). In this series of 16 patients, 1 experienced a bowel injury. Given its limitations, this method is unlikely to prove successful in overweight or obese patients. Rare case reports of transhepatic, transiliac, and trans-sciatic punctures have been described; however, such approaches should be considered only in the highly selected patient and done in conjunction with CT guidance and the interventional radiologist (Matlaga et al, 2006b).

Laparoscopic assistance has been used during PCNL to ensure a safe percutaneous access tract into the kidney by mobilizing and displacing any overlying intestines and directly observing the needle puncture into the kidney (Fig. 53-10). This was first described by Eshghi and associates (1985), and others have followed suit since then (Holman and Toth, 1998; Maheshwari et al, 2004; Gowel et al, 2006; Matlaga et al, 2006b; El-Kappany et al, 2007; Elbahnasy et al,

2011). Excellent stone-free rates are reported and overall morbidity is low. Most of these techniques use a Trendelenburg position to mobilize the intestines during a transperitoneal procedure. To minimize the risks of urinary leakage to the peritoneal cavity, appropriate postoperative drain placement is recommended. Zafar and Lingeman (1996) have described a simultaneous laparoscopic nephrostomy closure and ureteral catheter placement during pelvic kidney PCNL, thereby avoiding the need for an intra-abdominal drain. An entirely extraperitoneal approach to minimize the risk of intraperitoneal leakage has also been described (Holman and Toth, 1998).

Purely laparoscopic or robotic approaches to pelvic and ectopic kidneys provide high success with low morbidity and are particularly appealing treatment options when simultaneous repair of UPJO is planned (Chang and Dretler, 1996; Hoenig et al, 1997; Kamat and Khandelwal, 2004; Nayyar et al, 2010; El-Bahnasy et al, 2011). The concept is the same as for horseshoe kidneys: A pyelotomy is made to clear renal pelvis stones, and a flexible nephroscope and stone basket are then inserted through one of the laparoscopic trocars to access and clear calyceal stones. Stone-free rates of 80% to 100% have been reported (Ramakumar and Segura, 2000; Atug et al, 2005; Masson and Hoenig, 2008). Most authors use a transperitoneal approach, although Gaur and colleagues detail a retroperitoneal approach (Gaur et al, 1994).

For kidney stones in ectopic and horseshoe kidneys, SWL is a reasonable treatment option when stones are smaller than 1.5 cm and there is no UPJO or demonstration of poor renal drainage. URS may also be reasonable for stone burdens less than 2 cm, although they may require multiple treatment sessions. For stone burdens of 2 cm or more, PCNL or laparoscopy should be the initial treatment; a combination of the two procedures is expected for pelvic kidneys. When UPJO is confirmed, laparoscopy is the treatment of choice because it can address the stones and provides the highest success rate for UPJ repair.

Lower Pole Calculi

The preferred treatment of lower pole renal calculi has generated appreciable controversy over the last few decades (Tolley and Downey, 1999; Raman and Pearle, 2008; Yuruk et al, 2010). Regarding non-lower pole intrarenal calculi, stones within the lower pole tend to have worse surgical stone clearance rates compared with other locations when stratified by size and composition. The management strategy for lower pole stones continues to evolve as ureteroscopic capabilities improve and the limitations of the newer generations of shock wave lithotripters become more evident (Fig. 53-11).

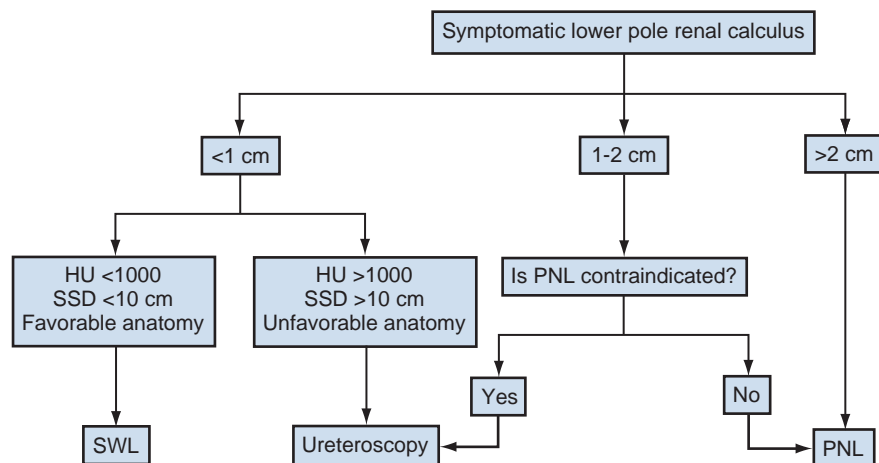

Figure 53-11. Treatment algorithm: lower pole stones. HU, Hounsfield unit; PCNL, percutaneous nephrolithotomy; SSD, skin-to-stone distance; SWL, shock wave lithotripsy. (Modified from Galvin DJ, Pearle MS. The contemporary management of renal and ureteric calculi. *BJU Int* 2006;98:1283-8.)

As discussed previously in the section on stone factors, overall stone burden is the main driver of treatment decisions for lower pole stones. Treatment decisions are most conveniently divided into stone burdens less than 1 cm, stone burdens of 1 to 2 cm, and stone burdens greater than 2 cm. Lower pole kidney stone burdens 2 cm or larger in size are best approached with PCNL because the collective evidence shows that PCNL offers a considerably higher stone-free rate in a single procedure than URS or SWL. For lower pole stone burdens of 1 cm to 2 cm, PCNL remains the most efficient treatment option, although it is more invasive, and is preferred when prior URS or SWL attempts have been unsuccessful. Ureteroscopy is the treatment modality of choice when PCNL is completely or relatively contraindicated and is a reasonable first-line option in experienced hands. In general, SWL results are disappointing for lower pole stone burdens over 1 cm, and therefore SWL should not be recommended as an initial treatment modality for such stones. For lower pole stones 1 cm or less, stone characteristics and patient factors become relatively more important than for larger stone burdens and should be incorporated into treatment recommendations. Stone burdens 1 cm or less in size may be reasonably approached with any modality including observation if completely asymptomatic, although future stone disease progression is likely. Lower-density stones that are less dense in nature and are in nonobese patients

without acute lower pole infundibulopelvic angles are among the few in the lower pole for which SWL provides a reasonable chance of success. Meanwhile, URS, with improved ureteroscope and instrumentation, has allowed improved access into the lower pole and expanded its use. Finally, PCNL should be used for stones that have failed less invasive treatment modalities or are extremely large or dense.

Historically, shortly after its clinical dissemination, it was realized that SWL provided unsatisfactory results for larger lower pole stones ([Consensus conference, 1988](#)). In fact, multiple series over the last 20 years have shown stone-free rates of approximately 50% or less for lower pole stones 1 to 2 cm, and less than approximately 30% for lower pole stones larger than 2 cm ([Table 53-1](#)). It was hypothesized that the gravity-dependent nature of the lower pole and certain lower pole anatomic characteristics may impede stone clearance ([Sampaio and Aragao, 1992, 1994](#); [Elbahnasy et al, 1998](#)). Sampaio and Aragao executed a series of elegant anatomic studies to better define the anatomy of the lower pole by creating polyester resin endocasts of the pelvicalyceal collecting system using adult cadaveric kidneys. They hypothesized that a number of different lower pole anatomic features may reduce stone passage, including a narrow lower pole infundibulum (width <4 mm), an acute lower pole infundibulopelvic angle (<90 degrees), and multiple lower pole infundibula rather than a single infundibulum ([Fig. 53-12](#)).

*Computed tomography-measured outcome.

Figure 53-12. Measurement scheme for lower pole anatomy. Lower pole infundibular length: measure A to B. Lower pole infundibular width: measure C to D. Lower pole infundibulopelvic angle: measure QRS angle. (From Albala DM, Assimos DG, Clayman RV, et al. Lower pole I: a prospective randomized trial of extracorporeal shock wave lithotripsy and percutaneous nephrostolithotomy for lower pole nephrolithiasis—initial results. *J Urol* 2001;166:2072–80.)

Similar findings have been demonstrated in subsequent investigations, suggesting that lower pole infundibular length greater than 3 cm, infundibular width less than 5 mm, and infundibulopelvic angle less than 70 degrees inhibit lower pole stone clearance during SWL (Sabnis et al, 1997; Elbahnasy et al, 1998). It is interesting to note that other studies have shown no effect of lower pole anatomy on stone clearance after SWL (Albala et al, 2001; Sorensen and Chandhoke, 2002).

In an attempt to improve stone clearance rates after SWL of lower pole calculi, a number of supplemental therapies have been proposed and examined. McCullough (1989) anecdotally reported that postural drainage may assist in the elimination of retained fragments from dependent calyces. Brownlee and associates (1990) subsequently treated patients with residual lower pole fragments with controlled inversion therapy, using intravenous hydration, inversion, and percussion. D'a Honey and associates (2000) reported a pilot study to determine whether mechanical percussion with inversion therapy and furosemide-induced diuresis can move stone fragments out of the lower pole of the kidney. At a mean time of 63 days after SWL, this group reported an 83% stone passage rate. In a subsequent study, Pace and associates (2001) compared the effectiveness of mechanical percussion, inversion, and furosemide-induced diuresis with observation for elimination of lower calyceal fragments after SWL. They reported that 40% of patients with residual lower pole fragments treated with this regimen became stone free compared with 3% in the observation group; the observation group was then treated with this regimen as part of a crossover design, and 43% were rendered stone free.

Chiong and colleagues (2005) performed a similar study and showed that percussion, diuresis, and inversion therapy improved

stone-free rates after SWL for lower pole stones. A recent Cochrane review included the studies by Pace and colleagues and Chiong and colleagues and concluded that overall evidence was limited, but that percussion, diuresis, and inversion were safe, were well tolerated, and appeared to modestly aid in stone passage after SWL (Liu et al, 2013). Other authors have reported lower pole irrigation techniques as adjuncts to SWL (Nicely et al, 1992; Graham and Nelson, 1994). More recently, pharmacotherapy with potassium citrate and thiazide diuretics has been described (Soygur et al, 2002; Arrabal-Martin et al, 2006). However, at this point in time none of these techniques has gained widespread acceptance.

The superiority of PCNL over SWL in clearing lower pole stones first became widely evident in a meta-analysis performed by Lingeman and colleagues in 1994 (Lingeman et al, 1994). In this report, PCNL achieved an overall 90% stone-free rate compared with 60% for SWL. Subgroup analysis stratified by stone burden showed that stones 10 mm or smaller had a 74% clearance rate with SWL and 100% clearance rate with PCNL, whereas stones 10 to 20 mm had a 56% clearance rate with SWL and an 89% clearance rate with PCNL (see Table 53-1). An even larger difference was appreciated for lower pole stones larger than 2 cm, for which stone-free rates were 94% for PCNL and only 33% for SWL. On regression analysis, increasing stone size was associated with decreasing stone clearance for SWL but had no demonstrable effect on PCNL.

After these retrospective data, a number of prospective trials ensued confirming the dominance of PCNL over SWL for the vast majority of lower pole stones (Albala et al, 2001; Yuruk et al, 2010). In the multicenter, prospective, randomized Lower Pole I study by Albala and associates (2001), stone-free rates as evaluated by nephrotomograms at 3 months after treatment were 95% for PCNL and only 37% for SWL. Stone-free rates for SWL were particularly low for stones 10 mm and larger: 23% for stones 1 to 2 cm, and 14% for stones larger than 2 cm. Yuruk and colleagues (2010) randomized 90 patients with lower pole stones 2 cm or smaller to SWL, PCNL, or observation. PCNL achieved a 97% stone-free rate compared with a 55% stone-free rate with SWL when patients were assessed at 3 months after treatment. As an additional component of this study, dimercaptosuccinic acid (DMSA) renal scintigraphy was performed in all patients, and a higher percentage of SWL patients (16%) were found to have developed renal scarring compared with the PCNL cohort (3%). Of note, these SWL patients had received three treatment sessions with an average of 1863 shocks per session. Ozturk and colleagues retrospectively reviewed 221 SWL, 144 PCNL, and 38 URS procedures and showed a 94% success rate with PCNL, a 76% success rate with SWL, and a 73% success rate for URS (Ozturk et al, 2013).

In an analogous fashion, SWL has been compared with URS for lower pole stone treatment, and the most contemporary results favor URS, although this was not always the case. In the seminal prospective, multicenter randomized trial by Pearle and colleagues (2005) comparing URS with SWL for lower pole stones 1 cm or smaller, stone-free status was accomplished in 50% of URS cases and only 35% of SWL cases, although the difference was not found to be statistically significant. Not unexpectedly, the convalescence time was less, and the health care–related quality of life measures were better for the SWL cohort (Pearle et al, 2005). More recently, Sener and colleagues performed a single-center randomized trial comparing SWL with URS for lower pole stones 1 cm or less in diameter (Sener et al, 2014). Treatment success was defined as stone-free or residual fragments less than 3 mm, and patients with acute infundibulopelvic angles (<30 degrees) were excluded. Stone-free status was achieved in 100% of URS cases and 91.5% of SWL cases, although an average of 2.7 SWL sessions per patient were necessary.

Recent series evaluating outcomes for lower pole stone burdens of 1 to 2 cm further highlight the ascendancy of URS over SWL, especially with respect to treating increasing lower pole stone burden. Stone-free rates of 85% and higher have been reported for single-session URS compared with 54% to 68% for multisection SWL (El-Nahas et al, 2012; Resorlu et al, 2013; Singh et al, 2014). Moreover, re-treatment rates and auxiliary treatment rates are

consistently higher for SWL, whereas complication rates are commensurate between the two modalities. These studies echo the results of [Pearle and coworkers \(2005\)](#), as voiding symptoms and convalescence time are more favorable for SWL than URS.

Since the early reports of URS for lower pole calculi in the mid and late 1990s, endourology has witnessed considerable progress in instrument design and surgical technique. These, in turn, have made URS more effective than SWL in treating lower pole stones ([Elashry et al, 1996](#); [Grasso and Ficazzola, 1999](#)). Smaller ureteroscopes with improved tip deflection and better stone manipulation instruments aid in accessing and fragmenting lower pole stones. Nitinol stone baskets have been used to reposition stones from the lower pole to more optimal intrarenal positions for lithotripsy, such as the middle or upper pole calyces ([Kourambas et al, 2000](#)). Stone-free rates approaching and exceeding 90% have been reported when stones were repositioned out of the lower pole, compared with stone-free rates closer to 80% when stones were fragmented in situ within the lower pole ([Kourambas et al, 2000](#); [Schuster et al, 2002](#)). Furthermore, contemporary URS outcomes appear to depend on lower pole infundibulopelvic angle, as was shown by [Resorlu and colleagues \(2012b\)](#), who found that URS was successful in 91% of cases when the angle was greater than 45 degrees versus only 65% of the time with more acute angles. In this same study, infundibular length and width did not affect URS outcomes.

Given the advancements in ureteroscopic design and technique, a number of investigators have sought to compare URS and PCNL for lower pole stones ([Kuo et al, 2003](#); [Bozkurt et al, 2011](#); [Kirac et al, 2013](#)). The Lower Pole Study Group compared URS and PCNL for lower pole stones of 1 cm to 2.5 cm. PCNL achieved a 71% stone-free rate, whereas URS achieved a 37% stone-free rate as determined by CT. The length of hospitalization was shorter for those undergoing URS; however, overall convalescence was not statistically different and was attributed to ureteral stent-related morbidity in the URS cohort ([Kuo et al, 2003](#)). [Bozkurt and associates \(2011\)](#) retrospectively compared outcomes between PCNL and URS for lower pole stones of 1.5 cm to 2 cm. Single-stage stone-free rates of 93% (PCNL) and 89% (URS) were appreciated. The PCNL group required more blood transfusions, but otherwise complications were similar between groups. It is important to recognize that this was not a randomized study, and patients with unfavorable lower pole anatomy (acute infundibulopelvic angles, small infundibular width) were preferentially treated with PCNL.

The same group also retrospectively compared URS with mini-PCNL for stones smaller than 1.5 cm and found equivalent stone-free rates of 89% between the two modalities. Not surprisingly, operative time, mean fluoroscopy time, and length of hospital stay were longer for PCNL ([Kirac et al, 2013](#)). Taken collectively, these data suggest that URS performed by clinicians experienced with the technique can produce excellent stone-free rates approaching those of PCNL. **The key to excellent URS outcomes appears to be careful patient selection, which includes those patients with favorable lower pole anatomy (nonacute lower infundibulopelvic angle, wide lower pole infundibulum).**

Not enough data exist to determine the optimal place for mini- and micro-PCNL in the treatment of lower pole stones, although initial results are encouraging in terms of both stone clearance and overall morbidity.

URETERAL CALCULI

Just as for renal calculi, the urologists's armamentarium to surgically treat ureteral stones consists of four minimally invasive modalities including SWL, URS, PCNL, and laparoscopic or robotic-assisted stone surgery. Open ureteral stone surgery is rarely performed when access to minimally invasive modalities exists and is often reserved for instances in which less invasive options have failed. There appears to be an evolving paradigm shift in the surgical treatment of upper tract stones, with an increasing use of URS and a reciprocal decreasing use of SWL for upper urinary tract stone disease ([Lee and Bariol, 2011](#); [Ordon et al, 2014](#)). Determining the

KEY POINTS: RENAL CALCULI

- SWL success is highest in stones 1 cm or smaller, 800 to 900 HU or lower, and in a non–lower pole location.
- PCNL offers the highest successful stone treatment for stones larger than 2 cm (including staghorn configuration), across all density measurements, and in all intrarenal locations.
- URS offers excellent success for all stone locations, although it may have decreased effectiveness in the lower pole.
- URS may be safely performed in patients with active anticoagulation or antiplatelet therapy.
- The outcomes of PCNL and URS are independent of the patient's BMI, whereas SWL success falls with increasing obesity.
- Stones that are symptomatic, obstructing, or associated with infections should be treated to ensure clearance.

optimal treatment for a given patient is not always straightforward and depends on stone-related factors, clinical factors, and technical factors ([Box 53-4](#)). It is the interplay of these factors and the familiarity of the urologist with each surgical technique that ultimately determine the best treatment modality for a given patient. The purpose of this section is to provide a framework to help guide the urologist in matching a given patient's unique clinical situation and ureteral stone disease characteristics to the most effective and least morbid surgical therapy.

Natural History

When a renal calculus begins to pass, it moves from the kidney into the UPJ and into the ureter proper. At that point, depending on the size of the stone relative to the ureter throughout its course, the stone will begin to obstruct the kidney. The first manifestation of this is an increase in the intra-collecting system pressure, which will stretch the renal pelvis, calyces, and renal capsule. It is during this phase that the traditional colic of a stone episode will begin.

This increase in intraluminal pressure will increase the hydrostatic pressure exerted on the walls of the renal pelvis and ureter, which can cause the failure of normal peristalsis. Pressure further increases at that point, with direct transmission to the nephron tubules, with a resulting drop in the glomerular filtration rate (GFR). Pressure will subsequently decrease to the levels that were present before obstruction developed, usually within 12 to 24 hours. Accordingly, the renal colic episode caused by a stone is often limited to severe pain from the acute renal stretch, followed by gradual resolution of the pain. Further movement of the stone

down the ureter can relieve the pressure and reobstruct further distally, explaining the intermittent nature of renal colic as a stone passes.

Long-term obstruction can cause permanent damage to the kidney's function; therefore, regardless of the absence of pain or infection, a stone must either pass spontaneously or be surgically treated. Key to the passage of a stone is ureteral peristalsis, not hydrostatic pressure (Lennon et al, 1997). When the ureter is not otherwise obstructed, the chief determinant of stone passage is the diameter of the stone in its transverse orientation (Ueno et al, 1977). Next most important is the location of the stone within the ureter at presentation, with a review of the literature demonstrating a 71% chance of passage of a distal ureteral stone versus 22% for proximal stones (Morse and Resnick, 1991). Additional evidence supports the idea that the likelihood of spontaneous passage may be directly related to stone location at the time of presentation (Hubner et al, 1993; Coll et al, 2002).

With respect to size as a predictor of spontaneous passage, meta-analysis of the available literature (as described in the AUA ureteral stone guidelines) demonstrates a 68% chance of passage for stones 5 mm or smaller, and an estimated 47% chance for stones 6 to 10 mm in size (Preminger et al, 2007). These rates can be enhanced with medical expulsive therapy (MET) using either calcium channel blockers (such as nifedipine) or α -receptor blockers (such as tamsulosin). α -Blockers appeared to offer an overall greater increase of spontaneous passage, with an absolute increase in chances of passage calculated at 29% across all stones. Thus, for ureteral calculi 5 mm or smaller, MET with expectant management is a reasonable therapeutic choice (Table 53-2).

Pretreatment Assessment

The pretreatment assessment, including medical history, imaging, and laboratory testing, for ureteral stones is similar to that for renal stones, and the reader is directed to the previous section on this topic in the renal calculi section of this chapter. Particular attention should be directed toward the duration of symptoms, given the fact that long-term obstruction can result in irreversible nephron loss. Any suggestion of fever in the setting of a ureteral stone strongly suggests the presence of infection proximal to the point of obstruction, and, regardless of how the patient appears at presentation, there should be a low threshold to proceed with urgent or immediate urinary tract drainage.

Specific symptoms may give clues to the course of the episode: New-onset urgency and frequency may herald a stone at the UVJ irritating the bladder, or the sudden relief of flank pain might indicate either passage or forniceal rupture as the pressure in the collecting system dramatically decreases. Assessment of renal function is paramount because ureteral stones are often obstructing at the time of presentation, and therefore renal function may be impaired

by obstruction, dehydration, or a combination of both. The associated physiologic stress of an acutely obstructing stone can lead to white blood cell (WBC) demarginalization and an elevated serum WBC count. Thus, leukocytosis in these patients may or may not represent an actual infection. In addition, it should be kept in mind that urinary tract stones frequently lead to pyuria and leukocyte esterase positivity on urinalysis, and these findings do not always represent an active UTI. However, if there is any concern regarding an associated UTI, then the immediate focus should be on urinary tract decompression rather than definitive surgery.

Stone Factors

Treatment Decision by Localization

Proximal and Mid-Ureter. The chief determinant of the optimal treatment for calculi in these locations is size. As previously mentioned, those which are more proximal and greater in size are significantly less likely to pass spontaneously. There is a paucity of data on the effectiveness of MET use in proximal and mid-ureteral stones, although since many of these stones do migrate distally, presumptive use of MET is not contraindicated (Hollingsworth et al, 2006; Seitz et al, 2009).

For stones that do not move in a reasonable time frame, or in the setting of recurring severe pain, or if the patient prefers, surgical therapy is indicated. Primary options include SWL and URS, although PCNL and antegrade nephroscopy may be indicated for select cases. Pooled data, as evaluated in the AUA ureteral stone guidelines, have defined outcomes in proximal and mid-ureteral stones (of all sizes) in patients who underwent SWL, with overall 82% and 73% treatment success rates, respectively (Preminger et al, 2007). When considering proximal ureteral stones that are 1 cm or smaller, SWL success rises among these pooled series to 90% (85% to 93%), and 84% (65% to 95%) for mid-ureteral stones. For stones larger than 1 cm, rates of complete stone clearance drop in both groups, to 68% for proximal and 76% for mid-ureter stones.

Similarly, the guidelines pooled numerous studies to evaluate outcome success for URS for these locations and sizes, demonstrating an overall success of 81% for proximal and 86% for mid-ureteral stones (Preminger et al, 2007). Calculi 1 cm or smaller again demonstrated higher success rates in both groups than did larger stones. A further breakdown of selected studies assessing stone-free rates after ureteroscopy for proximal ureteral stones is shown in Table 53-3.

It is interesting to note that the likelihood of postoperative results requiring additional procedures was 1.5 with SWL for these larger stones, and only 1.07 for URS. Of related interest, the cost-efficiency of management of proximal ureteral stones has been shown to be superior for URS when compared with SWL, when used as the initial treatment procedure (Lotan et al, 2002).

For very large proximal ureteral calculi not amenable to either SWL or URS (including large or dense stones, severe inflammatory response at the site of stone impaction that prevents passage of a guidewire from below, or associated ureteral pathology), a **percutaneous and antegrade approach may be ideal** (Maheshwari et al, 1999). Depending on the exact location within the ureter and calyx for percutaneous entry, such stones may be amenable to either rigid or flexible endoscopy. The opportunity to clear stone fragments using the access tract may offer optimal success for these challenging stones.

Lastly, laparoscopic and robotic ureterolithotomy have been described for proximal and mid-ureteral calculi, with success rates for stone clearance in selected cases of 93% to 100% (Hemal et al, 2010; Yasui et al, 2013). Significant discussion regarding such an approach, in many cases significantly more invasive than SWL, URS, or PCNL with antegrade endoscopy, should be undertaken with the patient when considering this option.

It is important to note that stones in a mid-ureteral location are typically handled in much the same way as proximal calculi, although some considerations relative to the pelvic anatomy will apply. With respect to SWL, the presence of the bony structures lying posterior to the ureter at this level can interfere with fluoroscopic or plain film imaging of the stone, as well as pose challenges to positioning the patient so that shock wave energy does not pass through the bone. Oblique or prone positioning may be required for SWL at this level.

Finally, URS for the mid-ureteral stone can often be accomplished with a semirigid ureteroscope; however, limitations caused by the iliac vessels, particularly in male patients, may be encountered. In addition, proximal migration of these stones can sometimes present a challenge with semirigid instrumentation. The availability of flexible ureteroscopes and the skills to perform flexible URS will improve the overall success rates and decrease complications (Perez Castro et al, 2014).

Distal Ureter. As discussed earlier, distal stones are most likely to pass with observation or MET (Preminger et al, 2007). The most typical site for impaction in this region of the ureter is at the UVJ; stones reaching this location often cause significant irritative symptoms owing to stimulation of the bladder, a clinical sign that helps localize them. When stones fail to pass, once again surgical therapy is indicated.

SWL and URS both remain the mainstays of treatment of distal ureteral stones. Once again, the AUA ureteral stone guidelines

TABLE 53-4 Ureteroscopic Treatment Outcomes for Distal Ureteral Calculi

		>10	93
Perez Castro et al, 2014	4446	67 mm ²	94

present a detailed review of pooled studies to identify success rates in both procedures. Among reviewed series using SWL for distal ureteral stones, the overall success rate was 74%. When considering stones 1 cm or smaller, an overall success rate of 86% was noted, whereas stones larger than 1 cm yielded a success rate of 74% (Preminger et al, 2007). In the same ureteral calculi guidelines analysis, URS for the distal ureteral calculus was shown to yield a 94% overall success rate, with stones 1 cm or smaller at 97% and over 1 cm at 93% success rate. A further breakdown of selected studies assessing stone-free rates after ureteroscopy for distal ureteral stones is shown in Table 53-4.

When comparing SWL with URS for the distal stone, reviewing the combined data for SWL in this fashion, one must consider the variation in lithotripters used that would affect overall outcomes in the multitude of series. In one randomized controlled trial comparing SWL with URS for distal ureteral calculi up to 15 mm in size, SWL was equally as effective as URS (100% in both groups), although it should be noted that this series used only the highly effective HM3 lithotripter (Pearle et al, 2001).

All Locations. Additional factors to consider in addition to stone-free success rates in the choice of therapy include the following:

- The complications of therapy such as sepsis, steinstrasse, ureteral stricture, and ureteral injury
- Anesthetic requirements
- Bleeding risk in patients with anticoagulation or antiplatelet therapy
- Recovery expectations
- Potential need for adjunctive procedures

Treatment Decision by Stone Burden

As described earlier, SWL success for ureteral stones at all locations is significantly affected by the total stone burden, just as it is for renal calculi: The larger the stone(s), the less effective the treatment (Preminger et al, 2007). As a specific example, the success rates for SWL at the distal ureter were 86% for stones 1 cm or smaller and 74% for those larger than 1 cm, and such differences held true for all locations. In contrast, URS had a much smaller degree of variation in terms of success based on stone burden: 97% success for stones 1 cm or smaller and 93% for those larger than 1 cm.

In a cost-comparison study of the management of ureteral calculi, Lotan and colleagues demonstrated that URS was associated with a lower cost than SWL for proximal stones, even before factoring in the higher adjunctive procedure rate associated with SWL (Lotan et al, 2002). The prospective comparison of SWL to URS for

distal stones by Pearle and colleagues showed that the overall complication rate was lower for SWL (9%) compared with URS (25%), though this was shown to mostly be related to urinary retention or significant colic requiring emergency evaluation or admission for pain control (and more likely to be clarified as a “minor” complication in the current literature) (Pearle et al, 2001).

Treatment by Stone Composition

As discussed earlier with respect to renal calculi, stone composition, if known or able to be predicted radiologically, can be useful in selecting the most appropriate therapy. Brushite (calcium phosphate) stones, calcium oxalate monohydrate, and cysteine stones are all more resistant to SWL therapy and can be expected to have better rates at all sizes and locations with URS (Rudnick et al, 1999; Ahmed et al, 2008). Similarly to renal calculi, assessment of ureteral stone density based on the Hounsfield units on CT scan can offer valuable predictive ability as to the stone-free rate using SWL (Joseph et al, 2002; Gupta et al, 2005; Wang et al, 2005; El-Nahas et al, 2007). In identical fashion as well, skin-to-stone distance—reflected in body habitus—can be measured on the CT scan, again allowing more informed prediction of SWL success.

Therefore, where possible to obtain prior stone composition data or prediction of composition based on radiologic studies, this should be undertaken so as to best inform the patient regarding choices of therapy.

It should be clear that it is imperative to tailor therapy choices to the individual patient, after careful discussion of outcomes of treatment: success rates, adjunctive procedures, and treatment-related morbidity. Both patient factors (body habitus, coagulation status, medical comorbidities) and stone factors (location, burden, composition) must be considered when selecting the optimal treatment for ureteral calculi.

Ureteral Anatomic Factors

Megaureter

Congenital megaureter most often is seen in children and usually represents an abnormality of the distal ureter or ureterovesical junction (UVJ) in which there is either an aperistaltic segment (causing obstruction) or incompetent UVJ (causing reflux), which yields dilation of the ureter. The first description of this condition in the literature was by Caulk in 1923 (Caulk, 1923). Subsequently a number of attempts to classify megaureter were undertaken, culminating in the consensus of a committee made up of members of the American Academy of Pediatrics, Society of Pediatric Urological Surgeons, and the Society for Pediatric Urology. These criteria have remained the most comprehensive system for classifying the megaureter (Stephens, 1977). Under this system, megaureters can be identified as refluxing, obstructed, and nonrefluxing and nonobstructed.

The majority of megaureters that are obstructed or refluxing are discovered when symptomatic during childhood and may require surgical repair. Reports of nonoperative, conservative management have been published, suggesting that some of these will resolve with the evolution of the UVJ as the child grows (Pitts and Muecke, 1974; Oliveira et al, 2000). The most typical operative repair has been ureteral reimplantation with, or without, tapering, but a recent report suggests that short-segment megaureters may be able to be successfully managed with endoureterotomy (Christman et al, 2012).

Megaureter has been associated with stones in both the pediatric population and rarely the adult population (Rosenblatt et al, 2009). Management strategies will significantly depend on the patient's surgical history, if any, and on recognition of any intrinsic ureteral obstruction that exists independent of the stone's location. Previously reimplanted ureters may be difficult to access in retrograde fashion, limiting the ability to place stents or approach stones via URS. In addition, an obstructed megaureter must be expected to lead to difficulties passing fragments after URS is performed.

Guidance as to ideal management is limited, as only case reports or small series have been reported in adults. In a nonobstructed megaureter, MET, SWL, and URS are all viable initial strategies. In the obstructed megaureter, strategies to manage both the stone and the underlying pathology have included the following:

- Retropulsion of the stones to the kidney, treatment of the stones via PCNL, and repositioning the patient to perform ureteroneocystostomy (Kumar et al, 2014)
- Ureterolithotomy with ureteroneocystostomy, open (Solinas et al, 2010; Demirtas et al, 2013) or robotic-assisted laparoscopic (Hemal et al, 2009)
- Ureteroscopy with endoureterotomy (in short-segment cases <3 cm), which would make concomitant ureteroscopic treatment of stone possible (Christman et al, 2012)

Clearly, when considering stone treatment in patients with a megaureter, one must choose a strategy that will account for both the stone and the underlying ureteral pathology.

Duplicated Collecting System

Duplication anomalies of the collecting system arise from ureteral bud abnormalities during gestation, occurring with an incidence of approximately 0.8% and following the Weigert-Meyer “rule” (Schlussel, 2007). This principle explains that in complete duplications, separate ureters enter the bladder with the more medial and inferior orifice draining the upper pole while the more lateral and superior orifice drains the lower pole. In incomplete duplications, there is only one ureteral orifice on that side within the bladder, with a variable level of bifurcation of the separate ureters which lead to the upper and lower moieties.

There are limited reports describing URS management of stones in partially or completely duplicated systems, but it is clear that ureteroscopy for these systems is little different from the more common single ureter. In the setting of a complete duplication, retrograde pyelography should be performed for each orifice to confirm which ureter contains the stone to be treated, and then treatment proceeds as usual.

In partial duplications, retrograde pyelography should be performed to locate the level of bifurcation in addition to the stone, with recognition of the fact that an intramural ureter location of the division of the two systems is most common (Rich, 1988). This can potentially inhibit visualization if the retrograde catheter is past the point of bifurcation. In this situation, ureteroscopy, following dilation of the ureteral orifice when necessary, can be used to directly inspect for the other moiety of the second ureter. In such cases, simultaneous stenting of both upper and lower pole ureteral segments may be necessary.

Ureteral Stricture or Stenosis

The presence of intrinsic ureteral obstruction will certainly affect the selection of ideal stone treatment in a number of ways. First, an untreated stricture or stenosis will preclude fragment passage and hence create an expectation of SWL failure. Second, the mechanism that is chosen to deal with the obstruction may facilitate and/or dictate how the stone will be managed. Finally, the physical properties of the stricture may mandate a particular course of action.

Most important, not every narrow point that is encountered in the ureter reflects a pathologic stricture, particularly when a stone may be impacted there. Inflammatory reaction and ureteral spasm may account for a significant portion of apparent obstructions that are encountered. In these situations, it is critical to recognize that overdilation of the ureter via endoscopic approach may cause localized ureteral injury (Eshghi, 1988). Despite this concern, balloon dilation of the ureter, when required for ureteroscopy, is safe and effective in the vast majority of patients (Huffman and Bagley, 1988). If the area of obstruction is felt to reflect spasm, placing a stent to allow passive dilation will facilitate a second-stage procedure in both pediatric and adult patients (Hubert and Palmer, 2005; Rubenstein et al, 2007).

When a definite stricture is present, underlying causes must be considered. Methods of dealing with ureteral strictures are covered elsewhere in this text and may provide the primary guidance for dealing with a ureteral stricture; a postretroscopy stricture is obviously significantly different from a radiation-induced one.

Endoureterotomy can be performed at all levels of the ureter; however, it will have a lower rate of long-term success in longer strictures (Wolf et al, 1997). Few data have been reported on the concomitant use of ureteroscopic laser lithotripsy at the time of an endoureterotomy or endopyelotomy, though there is a recognized potential for stone fragments to come to rest in the periureteral space and cause granulomatous inflammatory reaction and recurrent stricture (Dretler and Young, 1993). It is possible that, if URS is the preferred management strategy, endoureterotomy should be undertaken as a first stage, with placement of a ureteral stent to allow healing, and subsequent URS to manage the stone at a second stage.

Alternatively, consideration may lead one to proceed with open, laparoscopic, or robotic-assisted laparoscopic treatment for both the stricture and the stone in the same session. Numerous reports of laparoscopic and robotic-assisted ureterolithotomy have been reported, and the identical techniques and approaches used for management of a ureteral stricture can be used to also treat a ureteral stone in the same session (Dogra et al, 2013; Nasseh et al, 2013; Singh et al, 2013).

Technical Factors

Please see the Expert Consult website for details.

KEY POINTS: URETERAL CALCULI

- Conservative therapy, including MET, has its greatest success in stones 5 mm or smaller, but may still see fair success rates in stones up to 10 mm in size.
- Fever, or the presence of clinical or laboratory signs of UTI, may herald impending sepsis, a life-threatening condition; emergent drainage and decompression with either stent or nephrostomy should be undertaken.
- SWL and URS are both considered first-line therapies for stones at all locations within the ureter, although a higher rate of ancillary procedures should be expected with stones larger than 10 mm.
- Positioning challenges may be present for SWL in the mid-ureteral stone, requiring prone or oblique positioning for a clear blast path to the stone.

Clinical Factors for Upper Urinary Tract Calculi

Complete treatment planning for upper tract stones must incorporate the relevant clinical factors for a given patient, in addition to the stone-specific and anatomic factors (see Box 53-1). Certain patient conditions, anatomic aberrations, and underlying comorbidities assume significant importance in counseling patients on the relative risks and benefits of the different treatment options, as each can influence surgical outcomes and complications. Hence, a tailored approach to the individual patient is best.

Urinary Tract Infection

UTIs are common in the setting of upper tract calculi and should be adequately treated before any stone treatment. It is interesting to note that offending bacteria may reside deep within stones and prove impossible to eradicate without complete stone removal. Because of this, it may be difficult to completely sterilize the urine before stone surgery, in which case at least a short course of preoperative, culture-directed antibiotics is recommended. When infectious stones are suspected, every attempt at complete removal of stones should be undertaken because residual fragments commonly

harbor bacteria that can serve as a nidus for recurrent UTIs and promote rapid stone regrowth (Bichler et al, 2002). Therefore, PCNL and URS, when active stone extraction is possible, are preferred over SWL, in which stone clearance relies on physiologic stone passage and may take months to reach completion.

The rate of sepsis after PCNL or SWL is approximately 1% when preoperative urine cultures are negative. However, when preoperative bacteriuria exists or there is evidence of distal obstruction, the rate of sepsis associated with SWL for staghorn stones increases substantially (2% to 56%) and SWL should not be pursued (Zink et al, 1988; Lam et al, 1992a; Meretyk et al, 1992, 1997).

A UTI associated with an obstructing upper tract stone (ureteral or renal) represents a true urologic emergency and requires emergent urinary tract drainage. This is accomplished by either ureteral stenting or percutaneous nephrostomy. Attempts to definitively treat the obstructing stone should be postponed until the patient is stabilized and the infection is completely treated. Measures to treat the stone before patient stabilization and clearance of the infection risk worsening sepsis and death. In these instances, a urine culture from the obstructed segment is helpful to guide subsequent antibiotic therapy.

Renal Function

Assessment of underlying renal function becomes most important when there is suspicion that nephrectomy rather than stone removal is the treatment of choice. This scenario is encountered most frequently with staghorn stones, a history of recurrent pyelonephritis or renal abscess episodes, or xanthogranulomatous pyelonephritis and with chronic, relatively asymptomatic renal obstruction from ureteral stones. Renal imaging can provide clues to poor underlying renal function, including renal cortical atrophy or thinned renal parenchyma. In these instances, further functional renal studies, such as diuretic renography, can be used to quantify remaining renal function. In equivocal cases, temporary relief of obstruction with ureteral stenting or percutaneous nephrostomy is warranted, after which renal function can be reassessed. **The general consensus is that symptomatic upper tract stones located in renal units with approximately 15% or less split function should be considered for nephrectomy, and stone-specific, nephron-sparing treatments should not be pursued.**

A considerable body of evidence exists evaluating the effects of SWL and PCNL on renal function, while there is a relative paucity of data surrounding URS effects on renal function (Wood et al, 2011; Kartha et al, 2013; Sninsky et al, 2014). It is believed that URS induces minimal renal parenchymal damage, and although few studies have evaluated this directly at a histologic or biochemical level, no change in long-term renal function has been reported even after multiple URS treatments (Lee and Bagley, 2001; Sninsky et al, 2014). More robust and in-depth data exist and have consistently shown that SWL and single-access tract PCNL do not appear detrimental to total renal function over the long term (Chandhoke et al, 1992; Lee and Bagley 2001; Canes et al, 2009; El-Tabey et al, 2014; Sninsky et al, 2014). These results have been repeatedly shown in patients with renal insufficiency and with solitary kidneys for both SWL (Kulb et al, 1986; Chandhoke et al, 1992; Zanetti et al, 1992; Cass, 1994; Eassa et al, 2008; El-Assmy et al, 2008; Krambeck et al, 2008a) and PCNL (Alken, 1982; Marberger et al, 1985; Schiff et al, 1986; Agrawal et al, 1999; Singh et al, 2001; Canes et al, 2009; Kuzgunbay et al, 2010; Unsal et al, 2010). It is interesting to note that renal scintigraphy and single-photon emission computed tomography (SPECT) evaluation of kidneys after PCNL have also confirmed no changes in total renal function, although new focal cortical defects and reduced renal functional activity were seen in a minority of patients at the site of percutaneous renal access (Unsal et al, 2010; Akman et al, 2012a). The effects of multi-access tract PCNL on renal functional outcomes are mixed, with some investigators suggesting no effect on renal function (Moskovitz et al, 2006) and others showing renal deterioration (El-Tabey et al, 2014).

Considering the available evidence, as long as adequate renal function exists and nephrectomy is not being entertained, stone

The treatment of patients with ureteral calculi depends on multiple surgical technologies, and the availability of certain equipment will affect the possible options for treatment. Few operating environments will have all possible lithotripters, ureteroscopes, lithotrites, or stone-retrieval devices immediately available. In addition, the surgeon's preference and technical expertise will also affect the technique chosen. The majority of urologists and patients with stone disease in the United States do not have direct access to a fixed lithotripter on an unlimited basis. Therefore, treatment decisions may need to be modified according to lithotripter availability. Patients with symptomatic ureteral stones and no immediate lithotripter access have several options: They may be clinically observed with pain and emetic control; they can undergo placement of an internal ureteral stent to relieve the symptoms of renal colic (but then may develop stent-related morbidities); or they may have primary ureteroscopic removal of the stone, provided the requisite endoscopic equipment is available.

Because of recent pressures to decrease resource use, there is increasing emphasis in the modern medical environment on the reduction of cost. Such economic pressures have promoted the movement toward less invasive, more cost-effective therapy for patients with ureteral stones. Most studies performed in the United States have found that ureteroscopy is a more cost-effective intervention than SWL, a differential that is likely a result of the higher re-treatment rate associated with SWL. [Grasso and colleagues \(1995a\)](#) analyzed the cost of ureteroscopy and SWL for patients with ureteral calculi. When they compared outpatient ureteroscopic lithotripsy with SWL monotherapy, treatment costs were similar.

However, the addition of re-treatments and auxiliary procedures after SWL more than doubled the costs and weighed heavily against this modality's cost-effectiveness. [Kapoor and associates \(1992\)](#) compared the treatment costs of SWL and ureteroscopy: As a consequence of the significantly higher success rates (97% vs. 75%), ureteroscopy was the more cost-effective treatment approach. [Parker and associates \(2004\)](#) studied the cost associated with treating proximal ureteral stones and found that ureteroscopy was less costly, again as a consequence of its superior initial treatment success. Several investigators have approached the question of cost-effective treatment for ureteral calculi by constructing decision analysis models. [Wolf and associates \(1995\)](#) used a literature-based probability decision tree to determine the more effective and cost-efficient therapy for patients with distal ureteral calculi and found that although initial SWL was only slightly more expensive than ureteroscopy, the cost differential increased when additional complications and re-treatments were calculated. [Lotan and associates \(2002\)](#) also constructed a decision analysis model to determine the most cost-effective treatment for ureteral stones. Although observation was the least costly intervention, ureteroscopy was a less costly intervention than SWL for the treatment of stones at all locations in the ureter. A recent systematic review comparing the cost of SWL versus URS evaluated 10 different studies and found overwhelmingly that URS saved costs and achieved a higher stone-free rate for ureteral stones at all locations than SWL, though few of the studies were well designed. Thus, taken all together, **ureteroscopy is the most cost-effective treatment strategy for ureteral stones at all locations, after observation fails.**

treatment decisions should not, in general, be based on renal function. Rather, they should be based on stone-specific characteristics, renal anatomic factors, and other more relevant clinical factors.

Solitary Kidney

The main considerations in treating stones in congenitally, surgically, and functionally solitary kidneys include having a lower threshold to treat asymptomatic renal stones and ensuring sufficient renal drainage after stone treatment. By virtue of the fact that only one kidney exists or is functioning, a single, obstructing stone leads to total urinary obstruction and demands urgent attention. **It is for this reason that proactive treatment of asymptomatic stones, which might otherwise be observed when two functioning kidneys exist, is recommended in solitary kidneys.** The perils of complete ureteral obstruction, especially with concomitant UTI, can be life-threatening for patients with solitary kidneys. In the setting of clinical instability, UTI, or electrolyte abnormalities, initial urinary decompression via ureteral stenting or percutaneous nephrostomy drainage should be undertaken. Once the patient is clinically stable, and after treatment of any associated infection, definitive stone treatment may be pursued following the strategies outlined in the ureteral calculi section. Although not mandatory based on any meaningful evidence, it is highly advocated to place a ureteral stent after ureteroscopic manipulation, because temporary ureteral edema and occlusion caused by spasm or fragments can result in acute kidney injury and anuria.

Morbid Obesity

A BMI above 40 kg/m² is considered morbid obesity by the World Health Organization. Obesity, and in particular morbid obesity, can pose physiologic and technical challenges that must be accounted for when recommending stone treatment to such patients (Giblin et al, 1995; Freedman et al, 2002). Proper preoperative medical optimization and risk stratification are imperative, because obesity has been linked to a number of medical conditions that increase anesthetic risk, including cardiovascular disease, diabetes mellitus type II, and obstructive sleep apnea (among others). **Ureterorenoscopy and PCNL outcomes appear to be relatively independent of obesity status, whereas those after SWL are drastically worse.**

SWL is frequently suboptimal in morbidly obese patients, and in some cases it is actually impossible as patients may exceed the weight limitations of the lithotripter table or gantry. Many studies have shown increasing BMI to be a negative prognosticator for stone-free status after SWL (Ackermann et al, 1994; Portis et al, 2003). Moreover, the significant adipose tissue found in the morbidly obese can attenuate x-ray through-transmission, making it difficult to localize stones with fluoroscopy. If the stone is visible but located beyond the F2 focus of the lithotripter, a blast path technique may be used in which the stone is targeted along the same axis as the F2 focal point and relies on high pressures, though slightly defocused, generated beyond F2 to fragment the stone (Whelan et al, 1988; Locke et al, 1990). Given this, it is often necessary to use higher energy settings in obese patients, and lithotripters offering the highest peak pressures and longest focal length are preferred.

Skin-to-stone distance, or the distance between the SWL transducer and stone, has emerged as an important factor affecting SWL outcomes and is readily measured on axial CT slices. In general, the larger the skin-to-stone distance, the worse the fragmentation during SWL. Many studies have shown that **SWL outcomes worsen when skin-to-stone distance exceeds 10 cm** (Pareek et al, 2005; El-Nahas et al, 2007; Wiesenthal et al, 2011; Foda et al, 2013). Furthermore, Pareek and colleagues (2005) found that skin-to-stone distance was a stronger predictor of stone-free status than BMI. Perks and associates (2008) reviewed SWL in 111 patients with solitary stones 5 to 20 mm in size and found the best treatment success (91%) for skin-to-stone distances below 9 cm and stone attenuation below 900 HU, and the lowest treatment success (41%) for skin-to-

stone distances greater than 9 cm and stone attenuation exceeding 900 HU.

More recently, excessive visceral fat, as measurable on noncontrast CT, has proved to be a useful prognosticator for SWL outcomes. Indeed, increasing abdominal circumference, visceral fat, subcutaneous fat, and perirenal and pararenal fat are all associated with decreasing stone-free rates after SWL (Juan et al, 2012). Taking this one step further, Zhou and colleagues (2013) demonstrated that increasing visceral fat was an independent predictor of uric acid stones. Hence, a trial of urinary alkalinization is recommended in obese patients with radiolucent stones, a low urinary pH, and no other indications for urgent decompression.

PCNL in the morbidly obese is feasible and reportedly safe but also requires some technical modifications. Extra-long instruments (fascial dilators, access sheath, nephroscope, stone graspers) may become necessary, and mobility around the collecting system from a given access tract may be hindered by the long tract length. **Most available data confirm that stone-free rates are not affected by obesity, although there is some suggestion that stone-free rates are lower, and major complication rates are higher, in the morbidly obese** (Pearle et al, 1998; Koo et al, 2004). El-Assmy and associates (2007) and Kuntz and colleagues (2014) found no difference in stone-free rates, complications, auxiliary procedure rates, or length of stay among patients stratified by BMI, and proved that “tubeless” PCNL could be performed safely in these individuals. It is interesting to note that the CROES PCNL global study found equivalent stone-free rates for normal, overweight, and obese cohorts (approximately 80%), but significantly lower stone-free rates for the morbidly obese group (65.6%) (Fuller et al, 2012). Overall complication rates did not differ either among groups, although a greater percentage of major complications (Clavien-Dindo III to V) were found in the morbidly obese (10.5%) relative to the other groups (3.5% to 3.9%).

URS success and safety do not appear to change in the morbidly obese (Dash et al, 2002; Preminger et al, 2007; Natalin et al, 2009). Accordingly, URS may be the preferable treatment modality for obese patients without exceedingly complex or large stone burdens. Chew and colleagues (2013) performed a multicenter trial comparing URS in patients with normal BMIs with those considered overweight or obese; no significant difference was found in stone-free rates. Aboumarzouk and colleagues (2012c) performed a systematic review of URS in obese patients (mean BMI 42.2 kg/mm²) and found an excellent pooled stone-free rate (87.5%), mean operative time (97.1 minutes), and complication rate (11.4%).

Old Age and Frailty

Recently the concept of frailty has gained considerable attention in the surgical literature, although it has been somewhat slow to permeate into the field of urology. There is mounting evidence to suggest that the degree of frailty a patient exhibits, rather than his or her chronologic age, is a more robust predictor of postoperative complications (Makary et al, 2010; Revenig et al, 2014). At present, there are limited data on the effects of frailty on stone treatment outcomes; however, extrapolating from the available frailty literature in other fields, the frailest of patients may be better served with less invasive stone treatments (URS or SWL). Resorlu and associates (2012a) conducted a multicenter, retrospective review of PCNLs in elderly patients and found that a higher Charlson Comorbidity Index score was associated with a significantly higher rate of severe medical complications and hemorrhage. Similarly, many elderly patients have less physiologic reserve to handle an acute, obstructing stone event well, or to successfully tolerate a drawn-out trial of passage. In these instances, a more direct treatment strategy with early relief of urinary obstruction is prudent.

A number of groups have looked at PCNL outcomes in elderly populations and have found essentially unchanged surgical success, albeit with a higher rate of complications. Doré and colleagues (2004) reviewed PCNL outcomes in 201 patients age 70 and older and found a stone-free rate of 70.8%. Early work by Stoller

and colleagues (1994a) showed that PCNL was safe in patients older than 65 years but was associated with more frequent blood transfusions (26% vs. 14%). Akman and colleagues (2012b) compared URS and PCNL outcomes in patients older than 65 years and reported excellent stone-free rates (93% for URS, 96% for PCNL), reasonable operative times (65 minutes for URS, 41 minutes for PCNL), and acceptable complication rates (10.7% for PCNL, 7.1% for URS). In the largest published series on the topic, no difference was appreciated in stone-free rates (79% vs. 82%) or length of hospitalization in elderly (median age 74 years) versus younger (median age 49 years) cohorts, but there was a higher overall complication rate (19.9% vs. 6.6%) in the elderly (Okeke et al, 2012).

Shock wave lithotripsy in the elderly is feasible as well, but it may be associated with an increased risk of perinephric hematoma. Dhar and associates (2004) found a 1.67-times increased risk of hematoma formation after SWL with every 10-year increase in patient age, although subsequent studies have not consistently borne this out. Reports on treatment success with SWL in the elderly are mixed, showing a trend toward lesser success for renal stones and no effect on ureteral stones (Delakas et al, 2003; Abe et al, 2005; Ng et al, 2007). Furthermore, URS does not appear to confer any known additional risks to the elderly.

Spinal Deformity or Limb Contractures

Patients with spinal deformities and limb contractures present a number of challenges that can be anticipated preoperatively. Despite its minimally invasive nature, SWL is often unsuccessful, and with high re-treatment and auxiliary procedure rates, because it can be difficult or impossible to properly position these patients on the lithotripter table. Moreover, stone targeting may be fraught with difficulties, as scoliosis and abnormal pelvic anatomy can preclude an acceptable shock wave blast path. Fragment passage can also be hindered by aberrant renal location and associated poor upper tract drainage. Few contemporary reports exist, but older studies show only modest stone-free results in this population, along with a frequent need for multiple treatment sessions (Neuwirth et al, 1986; Lazare et al, 1988).

PCNL and URS are good alternatives to SWL, and both have been used with good success, although special considerations are necessary with each (Rubenstein et al, 2004; Goumas-Kartalas et al, 2010; Resorlu et al, 2012c). For URS, patient anatomy may preclude rigid instrument use (cystoscopy and ureteroscopy). The use of ureteral access sheaths is encouraged, if they can be safely placed, because they can provide rapid re-entry into the otherwise challenging-to-access upper collecting system. PCNL remains the preferred method of stone treatment in many of these patients, particularly with large and complex stone burdens. Stone clearance rates with PCNL are no different than in the general population, although there is a greater need for secondary procedures. Furthermore, PCNL in these circumstances is associated with a higher rate of infectious complications (Culkin et al, 1990; Symons et al, 2006; Goumas-Kartalas et al, 2010; Nabbout et al, 2012). Given the abnormal anatomic relationships in these patients, preoperative CT of the abdomen and pelvis is essential in planning optimal renal access and may reveal the need for CT guidance or potentially even laparoscopic guidance in selected situations to avoid bowel or solid organ injury (Matlaga et al, 2003a).

Uncorrected Coagulopathy

Uncorrected coagulopathy is a contraindication to SWL and PCNL; however, URS can be successfully undertaken in such circumstances with little to no increase in surgical morbidity. When coagulopathies have been corrected, patients should be considered candidates for SWL and PCNL, assuming no other contraindications exist. Many instances of life-threatening retroperitoneal hemorrhage have been reported after SWL use in patients on continuous anticoagulant and antiplatelet agents (Ruiz and Saltzman, 1990; Streem and Yost, 1990; Katz et al, 1997; Zanetti et al, 2001; Sare et al, 2002; Alsaikhan and Andonian, 2011).

For patients with imperative indications to remain on antiplatelet therapy (e.g., recent coronary artery stenting) or anti-coagulant agents (e.g., high-risk atrial fibrillation, venous thromboembolic disease, or mechanical cardiac valves), URS with holmium:yttrium-aluminum-garnet (Ho:YAG) laser lithotripsy is the treatment modality of choice. Since Grasso and Chaliki (1998) first reported the safe use of URS and Ho:YAG laser lithotripsy in patients with uncorrected coagulopathies, numerous other reports have followed recapitulating not only the safety, but also the high efficacy of URS in these challenging scenarios (Watterson et al, 2002; Turna et al, 2008; Aboumarzouk et al, 2012b). Of note, Ho:YAG laser lithotripsy is preferred and is considered safer than other intracorporeal lithotripters (Watterson et al, 2002).

Prior Renal Surgery

Prior renal surgery or trauma can lead to fibrosis, scarring, and deformity of the intrarenal collecting system, which in turn can complicate renal stone surgery. This situation is less frequently encountered today because fewer open stone surgeries are performed worldwide. Prior renal surgery is not a contraindication to any form of renal stone surgery and presents no new specific concerns, in and of itself. Thus, all treatment modalities may be employed as necessary, given appropriate indications (SWL, URS, PCNL). Certain precautions should be taken, however; the possibility of poor renal drainage should be entertained, as previous surgery can predispose to infundibular stenosis and iatrogenic UPJO. If obstruction is found or suspected, a treatment modality other than SWL should be chosen. URS and PCNL may be used as previously described. Of note, during URS an infundibulotomy may be necessary to adequately access a stone trapped behind an area of infundibular stenosis. Nevertheless, stone-free rates of 79% after a single URS and 92% after a secondary URS have been described (Osman et al, 2012).

PCNL after prior open kidney surgery and after prior SWL has been described by multiple investigators. For the most part, prior renal surgery (open or SWL) has no effect on PCNL complication rates (Tugcu et al, 2008; Gupta et al, 2009a; Yuruk et al, 2009; Resorlu et al, 2010; Zhong et al, 2013). A single recent retrospective study found a higher need for renal angioembolization to control postoperative bleeding in patients with previous open nephrolithotomy; however, this finding has not been corroborated by others (Yesil et al, 2013). The effect of prior open surgery on stone-free rates is less consistent, with some studies showing rates that are worse (Gupta et al, 2009a) and others showing unchanged rates (Tugcu et al, 2008; Resorlu et al, 2010).

Prior SWL therapy can make salvage PCNL more difficult, as evidenced by longer operative times and lower stone-free rates (Yuruk et al, 2009; Zhong et al, 2013). This is the presumed result of stone fragment scattering after SWL and the tendency for some of the stones to embed suburothelially within the renal parenchyma. In fact, the more ineffective the prior SWL attempt (i.e., less fragmentation), the better the expected results from the following PCNL. Bon and associates (1993) found a 92% success rate for nonfragmented stones compared with a 64% success rate in patients with numerous fragments.

Urinary Diversion

Renal and ureteral stones in patients with urinary diversions present unique obstacles. Adequate preoperative imaging is essential to provide details on the anatomy of the urinary diversion and provide clues to possible routes to access the stone. It may also suggest the presence of urinary stasis and obstruction within the diversion, which if present should also be addressed to minimize the risk of stone recurrence. In general, SWL, PCNL and antegrade URS, retrograde URS, or a combination thereof can be exploited.

As in other instances, SWL should not be used in the setting of urinary obstruction. However, without urinary obstruction, a single session of SWL can achieve success rates of 60% to 65% (Deliveliotis et al, 2002; El-Assmy et al, 2005). Retrograde URS is usually

confined to flexible instruments, and redundant ileal conduits and large-capacity urinary reservoirs with some form of nonrefluxing ureteral anastomosis often require flexible instruments to locate the ureteral "orifices." Successful access to the upper urinary tract has been reported up to 75% of the time in urinary diversions, with a much lower rate seen in Indiana pouches (Hyams et al, 2009). Loopograms or pouchograms can aid in locating ureteral insertions when upper tract reflux exists. Alternatively, intravenous indigo carmine or contrast can be used as well. For patent ureteroenteric anastomoses, the judicious use of ureteral access sheaths can both facilitate upper tract re-entry and protect the anastomotic site.

For larger stone burdens and when retrograde access is not possible, PCNL becomes the treatment modality of choice, with a reported stone-free rate of 75% to 88% (Wolf and Stoller, 1991; El-Nahas et al, 2006; Hertzog et al, 2013). In addition, percutaneous access can allow antegrade URS to achieve access to the ureter when retrograde techniques fail. Complication rates of 8% to 30% have been reported for percutaneous approaches to stones in these patients. Percutaneous access may require ultrasound guidance if retrograde or antegrade contrast filling of the pelvicalyceal system is not possible.

Renal Transplants

The general consensus is to remove upper tract stones within renal transplants, as the consequences of an obstructing stone can be devastating. Indeed, because of the lack of innervation in renal transplants, obstructing stones do not manifest with typical renal colic. Rather, vague graft site discomfort, fevers, oliguria, hematuria, or rising creatinine may be the only presenting signs.

SWL has been described for stones in transplant kidneys and is an option for stones smaller than 1.5 cm; however, high re-treatment rates and auxiliary procedure rates should be expected (Klingler et al, 2002; Challacombe et al, 2005). Given that the renal allograft is located near the bony pelvis, prone positioning is often necessary. Antegrade and retrograde URS have been used to successfully treat transplant kidney and ureteral stones. Angled catheters and guidewires are often indispensable in achieving retrograde access, and prior placement of a percutaneous nephrostomy tube can facilitate antegrade URS and obviate the need for percutaneous tract dilation (Hyams et al, 2012). Stone-free rates of 67% to 92% have been reported, although no large series exist (Del Pizzo et al, 1998; Basiri et al, 2006).

PCNL remains the preferred treatment choice for large-burden stones (>1.5 cm) or if less invasive methods have failed. Stone-free rates ranging from 77% to 100%, similar to rates in the general population, have been reported (He et al, 2007; Krambeck et al, 2008b; Rifaoglu et al, 2008). When obtaining percutaneous access to transplant kidneys, CT or ultrasound guidance is advisable because there is a risk for intervening bowel. Furthermore, some reports describe difficulty with percutaneous access secondary to a fibrous capsule that develops around certain transplanted kidneys and may require use of metal fascial dilators to overcome. Percutaneous access with a 16-Fr peel-away sheath has been illustrated; this mini-PCNL technique is thought to carry a lower risk of surgical bleeding and still be of significant usefulness for these stones (He et al, 2007).

Duration of Ureteral Stone Presence

As discussed in the natural history section on ureteral calculi, after the initially reversible physiologic changes seen with acute ureteral obstruction, chronic ureteral obstruction can ultimately lead to permanent renal damage. Patients attempting to spontaneously pass a ureteral stone should be intermittently imaged to evaluate for persistent or worsening hydronephrosis and stone location and passage. Active stone treatment of any form is indicated when obstruction has persisted for approximately 4 weeks (Singal and Denstedt, 1997). Continued renal blockage after this time may lead to irreversible kidney damage (Vaughan and Gillenwater, 1971). Holm-Nielsen and associates (1981) reported that of 134 patients

with unilateral ureteral stones, one third of the patients with obstruction lasting more than 4 weeks developed irreversible renal damage. Similarly, Kelleher and associates (1991) found that sequential renal scintigraphy performed on 76 patients with obstructive ureteral calculi demonstrated an 18% incidence of reduced renal function (defined as a decrease in relative function greater than 7%).

KEY POINTS: CLINICAL FACTORS

- Definitive stone treatment should be undertaken only in the setting of sterile urine, although a negative urinalysis may be an applicable surrogate to negative culture.
- Morbid obesity significantly affects SWL success rate.
- Kidneys with inherent drainage problems, such as those with UPJO, infundibular stenosis, or ectopic or horseshoe configuration, need to have the underlying obstruction managed in addition to treatment of the stone.
- In kidneys with poor (<15%) function, nephrectomy may be the optimal treatment.

Evaluation of Outcome

Assessment and Fate of Residual Fragments

In the era of open stone surgery, residual fragments of any size suggested a failed procedure. In the modern era with the rise of endourology and the frequent use of SWL, URS, and PCNL, postoperative residual fragments are relatively common. However, the definition and optimal management of residual fragments continue to generate controversy.

With the increasing popularity of SWL in the 1980s and the observation that many patients retained small fragments of questionable clinical relevance after such therapy, the concept of **clinically insignificant residual fragments (CIRF)** was introduced and would become incorporated into the definition of a successful treatment outcome (Newman et al, 1988). These fragments were initially, and arbitrarily, defined as residual fragments 4 mm or less in diameter that were nonobstructive, noninfectious, associated with sterile urine, and in an otherwise asymptomatic patient (Newman et al, 1988). Since then, the term has been applied to fragments of various sizes, with most studies using a cutoff between 2 mm and 4 mm.

Therefore, since the introduction of SWL, treatment outcomes for patients with renal calculi have been reported by two different terms: stone-free rate and success rate. The stone-free rate is self-explanatory, but the success rate includes patients who are stone free as well as those with CIRF. These different methods of reporting treatment results, the lack of a standard definition for CIRF, and the various modalities used for assessing postprocedural stone-free status (KUB studies, nephrotomography, ultrasonography, CT) make the comparison of endourologic stone outcomes difficult. Further complicating matters is the fact that stone fragment passage after SWL is not immediate; as many as 85% of patients have radiologic evidence of residual fragments several days after SWL (Drach et al, 1986). Although most fragments pass spontaneously during the first 3 months after SWL, continued clearance can occur for more than 24 months after treatment (Chaussy and Schmiedt, 1984; Graff et al, 1988; Kohrmann et al, 1993).

In an attempt to better characterize the clinically meaningful success of any given stone treatment, Clayman and colleagues (1989) introduced the effectiveness quotient:

$$\frac{\% \text{ stone free}}{100\% + \text{retreatment} + \% \text{ auxiliary procedures}} \times 100$$

The effectiveness quotient accounts for the re-treatment rate, stone-free rate, and number of ancillary procedures and is useful in comparing results among different treatment modalities. For

example, the study by Netto and colleagues (1991) compared PCNL and SWL for the treatment of stones in lower pole calyces. The PCNL group had a 93.6% stone-free rate with no need for re-treatment, whereas the SWL group had a 79.2% success rate with a 41.6% re-treatment rate. The relative success rates for PCNL and SWL were not significantly different; however, a significant difference was appreciated when comparing the effectiveness quotients (93.7% for PCNL vs. 55.9% for SWL).

The term *clinically insignificant residual fragments* may be a misnomer because many small residual fragments eventually become clinically significant and symptomatic by dislodging and causing obstruction, serving as niduses for further stone growth, or acting as a source for persistent infections (Streem et al, 1996; Zanetti et al, 1997; Candau et al, 2000; Delvecchio and Preminger, 2000). Streem and colleagues (1996) reported that 43% of initially deemed CIRF became symptomatic at a mean follow-up of 23 months. Moreover, complete stone removal appears to decrease the risk of stone recurrence (Singh et al, 1975; Patterson et al, 1987; Newman et al, 1988). Stone recurrence rates of 6% to 15% have been reported for patients rendered stone free after SWL, compared with rates of 17% to 80% when residual fragments remained (Graft et al, 1988; Newman et al, 1988; Nijman et al, 1989; Beck and Riehle, 1991; Fuchs et al, 1991; Zanetti et al, 1991; Nakamoto et al, 1993). Residual fragments are most likely to pass when located within the ureter, and least likely to pass when located in the lower pole.

In a large review on SWL by Rassweiler and colleagues (2001), CIRF were found to spontaneously pass in 25%, remain stable in 55%, and become clinically significant in 20% of patients, with anywhere from 4% to 25% of patients requiring a subsequent intervention to address the residual fragment. A similar spontaneous passage rate of 25% to 30% has been reported by others (Streem and associates, 1997; Candau et al, 2000). When pooling the findings from the available prospective data, the probability that CIRF after SWL later become clinically significant increases with lower pole fragments, increasing fragment burden, increasing fragment number, and longer follow-up (Streem et al, 1996; Khaitan et al, 2002; Osman et al, 2005b).

Many investigators have noted that, after SWL, residual fragments are commonly localized to lower pole calyces no matter where the stone was treated in the kidney (Drach et al, 1986; Graft et al, 1988; Liedle et al, 1988; Zanetti et al, 1991; Kohrmann et al, 1993). It is interesting to note that the incidence of stone recurrence is greater in the lower pole calyces after SWL than it is after PCNL (Zanetti et al, 1991; Kohrmann et al, 1993; Carr et al, 1996). Furthermore, at 1-year follow-up there is a significantly greater rate of new stone formation in those treated with SWL, and the recurrent stones are more likely to be in the lower calyces. A plausible explanation for these results is that fine debris, undetectable by imaging, persists after SWL and, because of gravity, settles in the most dependent calyces and serves as a nidus for new stone formation. Supporting this hypothesis are the results from Carr and colleagues (1996) showing that de novo stone formation occurs significantly more often after SWL (22%) than PCNL (4%).

Stone-free rates after PCNL vary widely from 40% to well above 90%. However, as with SWL reporting, the definition of stone free is not consistent across studies (Park et al, 2007; Skolarikos and de la Rosette, 2008). Raman and colleagues (2009) found an 8% rate of residual fragments by CT scan, with approximately half located in the lower pole. Of the patients with residual fragments, 43% developed a stone-related event at a median of 32 months after initial PCNL. Fragments larger than 2 mm in greatest diameter were more likely to undergo a secondary procedure and independently predicted a postoperative stone-related event. Similarly, fragments located in the renal pelvis and ureter were associated with a stone event on multivariate analysis but also were associated with the highest likelihood of spontaneously passing (Ganpule et al, 2009; Raman et al, 2009).

Few investigators have evaluated the destiny of residual fragments after URS. The recent meta-analysis by the AUA and EAU revealed that residual fragments occur in 6% of cases for distal

ureteral stones, 14% of cases for mid-ureteral stones, and 19% of cases for proximal ureteral stones (Preminger et al, 2007). The limited data in which CT was used to evaluate residual fragment status after URS have shown stone-free rates of only 50% to 54% (Pearle et al, 2005; Portis et al, 2006). Expanding the definition of treatment success to also include fragments 2 mm or smaller improves the success rate to 62% to 84% (Portis et al, 2006; Macejko et al, 2009; Rippel et al, 2012). Schatloff and associates (2010) found that patients with residual fragments after semirigid ureteroscopy were significantly more likely to experience unanticipated medical visits (3% vs. 30%) and exhibited a trend toward more ancillary procedures (0% vs. 7%) and more frequent rehospitalization (0% vs. 10%). Over a 19-month period after URS, Rebuck and colleagues (2011) reported a 20% rate of unplanned stone events, a 22% rate of spontaneous passage, and a 57% rate of persistent residual fragments (≤ 4 mm).

In patients with infection-related calculi, the consequence of residual fragments is particularly harmful. Residual fragments may harbor offending bacteria and thus predispose to persistent infection. Furthermore, stone regrowth has been reported in up to 75% of such patients after SWL, compared with 10% of patients who experienced complete stone removal (Beck and Riehle, 1991; Zanetti et al, 1991).

For patients with metabolic stone disease, complete stone removal does not prevent stone recurrence, but it does prolong the intervals between symptomatic events and treatment (Chow and Streem, 1998). Thus, residual stones, including small stones, may not have an immediate clinical relevance but are likely to affect the patient's well-being in the long term.

The sensitivity of the method used to detect remaining fragments has important effects on the reported incidence and size of residual fragments. As stated, plain radiography, nephrotomography, ultrasonography, intravenous urography, and CT have all been used to evaluate residual fragments. Plain radiography, ultrasonography, and CT are used most frequently in contemporary practice. In the current era with the recognition that repeated radiation exposure from CT may be harmful, the routine use of CT scan for follow-up studies should be done cautiously and only when necessary.

In early studies investigating stone clearance after SWL, plain radiography was commonly used to determine stone-free status for radiopaque calculi and could detect opaque stone fragments as small as 2 mm (Thornbury and Parker, 1982). Plain radiography has a sensitivity of approximately 60% for detecting urinary stones (Mutgi et al, 1991; Assi et al, 2000; Ege et al, 2004; Johnston et al, 2009). However, Denstedt and coworkers (1991) reported that for patients with large renal calculi treated by a combination of PCNL and SWL, plain radiography overestimated stone-free rates by 35% and 17%, respectively, compared with flexible nephroscopy. Nephrotomography, although becoming obsolete in many centers, has proved superior to plain radiography in detecting residual fragments (Hjollund Madsen, 1972; Schwartz et al, 1984; Goldwasser et al, 1989).

Traditionally, ultrasonography has been inferior to plain radiography in detecting urinary calculi, with particular deficiency in detecting ureteral stones (Yilmaz et al, 1998; Older and Jenkins, 2000). The sensitivity of ultrasonography to detect urinary calculi over the last decade has ranged from 24% to 57% (Fowler et al, 2002; Ullusan et al, 2007; Viprakasit et al, 2012), although these results were potentially confounded because CT scans and ultrasounds were rarely done on the same day and infrequently performed by a dedicated uro-ultrasonographer. Kanno and colleagues (2014) recently reported a 70% ultrasound sensitivity in detecting renal stones when the ultrasound was done the same day as the CT, average patient BMI was 23, and all ultrasounds were performed by experienced ultrasonographers. Hence, even under the most favorable circumstances, ultrasound may still miss up to 30% of renal stones.

Despite its shortcomings, in detecting ureteral stones, ultrasound is highly effective in diagnosing hydronephrosis. In fact, some advocate for ultrasonography after all ureteroscopic procedures because silent obstruction has been reported to occur in certain, albeit rare,

instances (Weizer et al, 2002). A prospective study comparing the relative efficacy of abdominal radiography and renal ultrasonography versus excretory urography for the evaluation of asymptomatic patients 1 month after SWL treatment demonstrated that the combination of ultrasonography and abdominal radiography was as good as or better than intravenous urography in identifying residual stone fragments and hydronephrosis, suggesting that **routine radiologic evaluation of asymptomatic patients after SWL could be limited to abdominal radiography and ultrasonography** (Coughlin et al, 1989).

Although flexible nephroscopy may be considered the gold standard for assessment of residual stones after PCNL, its routine use has been challenged by studies showing the high sensitivity of CT in detecting residual stones after PCNL. **Pearle and coworkers (1999)** noted that CT had 100% sensitivity for detecting residual stones after PCNL in 36 patients evaluated with both CT and flexible nephroscopy. Selective use of flexible nephroscopy based on positive CT findings would have avoided an unnecessary procedure in 20% of patients. In a retrospective study of 121 patients who underwent CT after PCNL (including 59% stone-free patients and 16% patients with fragments of 1 to 3 mm), **Waldmann and associates (1999)** reported that routine nephroscopy would not have been required in 75% of cases. Given its wide availability and high sensitivity, CT has become the primary method for evaluation of residual stone fragments after PCNL. However, this must be balanced with the need to minimize unnecessary radiation exposure in patients.

KEY POINTS: RESIDUAL FRAGMENTS

- Many small residual fragments will eventually become clinically significant and symptomatic.
- In the setting of infectious stones, residual stones portend a future of UTIs and stone recurrence; therefore, aggressive treatment with removal of fragments is usually indicated.
- Risks for stone recurrence are higher in the setting of residual stone fragments, because stone growth on an existing crystal matrix is harder to prevent than spontaneous nucleation of new stones.

STONE REMOVAL: SURGICAL TECHNIQUES AND TECHNOLOGY

Intracorporeal Lithotripsy

Ureteroscopy and percutaneous nephrolithotomy (PNL) occupy an essential place in the treatment of urinary calculi as increasing technologic advancements allow easier access to stones in all parts of the kidney and ureter. In particular, improvements in ureteroscopic equipment emphasize the need for appropriate and effective miniaturized intracorporeal lithotripsy devices. Smaller ureteral stones can be extracted intact with endoscopic baskets or grasping devices after ureteral dilation, if necessary. However, larger ureteral stones require lithotripsy to permit the safe extraction of calculus fragments. The fragmentation of renal stones during PNL requires an approach different from that applied to ureteral intracorporeal lithotripsy. Although small and flexible endoscopic lithotrites are essential for the occasional difficult-to-approach kidney stone, renal stones can be visualized with a rigid nephroscope in most cases. In these situations, with a large kidney stone burden, the efficiency of the lithotrite is the most important requirement and size and flexibility are of secondary importance. The urologist who treats patients with urolithiasis thus requires an armamentarium of intracorporeal lithotripsy devices, each maximizing a different quality (e.g., size, flexibility, efficiency).

Four techniques are available for intracorporeal lithotripsy: electrohydraulic lithotripsy (EHL), laser lithotripsy, ultrasonic lithotripsy, and ballistic lithotripsy. These techniques can be divided into those lithotrites that are flexible (laser lithotripsy and EHL) and those that are rigid (ultrasonic and ballistic lithotripsy). This chapter will review the mechanisms, advantages, disadvantages, and surgical techniques of the various flexible and rigid intracorporeal lithotripters.

Flexible Lithotripters

Electrohydraulic Lithotripsy. EHL was invented in 1955 by Yutkin, an engineer at the University of Kiev, and was the first technique developed for intracorporeal lithotripsy (Grocela and Dretler, 1997). The first reported use of EHL outside the Eastern Bloc was in 1960, when a modified version of Yutkin's invention, the Urat-1, was used to fragment bladder calculi (Rouvalis, 1970). EHL was first applied to renal calculi during an open surgical lithotomy in 1975 (Raney and Handler, 1975). In 1985, Lytton reported the first experience treating patients with ureteral stones with a rigid ureteroscope and a 5-Fr EHL probe; no immediate or long-term complications were encountered (Green and Lytton, 1985). The use of smaller EHL probes through a flexible ureteroscope was first reported in 1988 (Begun et al, 1988).

The EHL probe is essentially an underwater spark plug composed of two concentric electrodes of different voltage polarities separated by insulation. When a current sufficient to overcome the insulative gap is applied, a spark is produced. The spark discharge

causes the explosive formation of a plasma channel and vaporization of the water surrounding the electrode. The rapidly expanding plasma causes a hydraulic shock wave followed by formation of a cavitation bubble (Fig. 54-1). Depending on the proximity of the probe to the stone surface, the collapse of the cavitation bubble may be symmetrical (at a distance of ~ 1 mm from the stone), resulting in a strong secondary shock wave, or asymmetrical (at a distance equivalent to a maximum bubble radius of ~ 3 mm), leading to the formation of high-speed microjets (Vorreuther et al, 1995; Zhong et al, 1997). Unlike in shock wave lithotripsy (SWL) the shock wave is not focused, so the stone must be placed where the shock wave is generated. The first EHL probes developed were of larger diameters (9 Fr) and, because of their size, had a narrow margin of safety. Later improvements in technology allowed the development of smaller probes, from 1.6 to 5 Fr, that were safer and had the ability to be passed through small-diameter, flexible ureteroscopes without occluding the irrigation or working channel. There is little difference in fragmentation ability among the different-sized probes, but the larger probes tended to be more durable (Segura, 1999). Subsequent improvements in the EHL generator allowed the surgeon more control over energy discharge, pulse, and duration. Although it was originally hypothesized to function optimally in a $\frac{1}{6}$ to $\frac{1}{2}$ normal saline solution, Denstedt and Clayman (1990) demonstrated that EHL works equally well in a normal saline solution, eliminating the hazard of irrigating the upper urinary tract with a hypotonic solution.

Advantages and Disadvantages. The major disadvantage of EHL is its propensity to damage the ureteral mucosa and its association with ureteral perforation. Raney (1978) reported that with a 9-Fr probe, 90% of ureteral stones could be successfully fragmented, but there was a 40% incidence of ureteral extravasation. Ureteral perforation remained an issue of concern with EHL in the ureter despite advancements in technology and technique. Hofbauer and coworkers (1995), in a prospective study of 72 patients, reported a perforation rate of 17.6% with EHL versus 2.6% with pneumatic lithotripsy. However, others have reported a lower rate of perforation, with a mean incidence of 8.5% recorded. Vorreuther and associates (1995) suggested that the mechanism of damage is the expansion of the cavitation bubble and thus injury may occur even when the probe is not in direct contact with the mucosa. The diameter of the cavitation bubble depends on the energy used and can expand to more than 1.5 cm when energies greater than 1300 mJ are employed. Therefore the risk for perforation is greater with higher energies, such as in treatment of a hard stone. Even with smaller probes and lower energy settings, perforation may occur if repeated pulses are applied close to the mucosa. Santa-Cruz and colleagues (1998), in a comparative in vitro study, reported that the holmium laser and EHL were associated with a higher risk for perforation compared with the coumarin pulsed-dye laser and pneumatic lithotripter. When the authors placed a 3-Fr probe 0.5 mm from the ureteral wall, perforation was induced with an average of 24 pulses. The risk for perforation may be higher for impacted stones associated with significant mucosal edema or if vision is

Figure 54-1. Photograph of liquid microjet produced by an asymmetrically collapsing cavitation bubble. (Courtesy Dr. Larry Crum.)

impaired by the minor hemorrhage that commonly occurs during EHL (Hofbauer et al, 1995).

As with most lithotrites, retrograde propulsion of calculi and fragments can occur during EHL and is more pronounced than with holmium:yttrium YAG lithotripsy (Teichman et al, 1997). In a series of 43 patients treated for proximal ureteral calculi, 14% required subsequent SWL for stones that migrated into the kidney (Yang and Hong, 1996). Placement of a basket or other retention device above the stone may prevent stone retropulsion. However, care should be taken not to activate the EHL device directly on the basket wires or the guidewire. Another disadvantage of EHL compared with holmium:yttrium-aluminum-garnet (YAG) lithotripsy is the larger number and size of fragments produced, especially for stones larger than 15 mm. The repeated passage of the ureteroscope to extract the multiple stone fragments produced during EHL may exacerbate mucosal irritation (Teichman et al, 1997).

EHL will successfully fragment 90% of stones. However, treatment failures may be due to a variety of stone compositions. Stone surface characteristics also may play a role in fragmentation efficiency; rough calculi have been reported to fragment more readily than smooth calculi (Basar et al, 1997). Although EHL successfully fragments most ureteral stones, the average 3-month stone-free rate is only 84% because some of the fragments created during lithotripsy and not removed may be retained in the ureter. Stone-free rates decrease with ureteral stones larger than 15 mm and are significantly lower than those reported for holmium:YAG lithotripsy (67% vs. 100%) (Teichman et al, 1997).

The advantages of EHL include probe flexibility, especially the smaller probes such as the 1.9 Fr, which allows intracorporeal lithotripsy throughout the entire upper urinary tract through rigid or flexible ureteroscopes. Only the holmium:YAG laser, configured with the 200- μ m fiber, offers comparable size and flexibility advantages (Elashry et al, 1996). The 1.6-Fr EHL probe may be even more flexible than the 200- μ m laser fiber (Poon et al, 1997).

EHL is also the least costly intracorporeal device, requiring the purchase of a comparatively inexpensive generator and probes. An average of 1 to 1.3 probes are used per case, except in instances of harder stones (e.g., calcium oxalate monohydrate stones), when two or more EHL probes may be needed (Elashry et al, 1996; Huang et al, 1998).

Technique. For intraureteral lithotripsy, the smaller 1.6- and 1.9-Fr probes should be used. The EHL fiber tip should be positioned 2 to 5 mm distal to the end of the ureteroscope to protect the lens system from being damaged when the probe is discharged. Before the EHL generator is activated the stone must be clearly visible. The probe is placed approximately 1 mm from the stone surface, a distance allowing maximum shock wave emission (Zhong et al, 1997). Initially, low voltage (50 to 60 V) and short intermittent or single pulses are used to enhance safety. The generator output is increased as needed to fragment the stone. However, it is recom-

mended that the treating physician limit the maximum output used in treating ureteral stones to minimize the risk for perforation. The goal of the treatment is to create fragments that can be removed with grasping forceps or a basket device or fragments that are likely to pass spontaneously. Attempts to reduce the stone to fragments smaller than 2 mm are not recommended because damage to the urothelium may occur (Denstedt and Clayman, 1990). After 50 to 60 seconds of firing, the insulation at the tip of the probe may peel away and at this time a new probe should be used (Segura, 1999).

Laser Lithotripsy. Laser is an acronym for light amplification by stimulated emission of radiation, which is a concise description of how a laser works. Laser energy is produced when an atom is stimulated by an external energy source, which creates a population of electrons in an excited state. These excited or higher energy electrons can release their excess energy in the form of photons or light energy. Laser light differs from natural light in that it is coherent (all photons are in phase with one another), collimated (photons travel parallel to each other), and monochromatic (all photons have the same wavelength (Floratos and de la Rosette, 1999)). These unique features of laser light allow considerable energy to be transmitted in a highly concentrated manner. Lasers are named after the medium that generates their specific wavelength of light; for example, the laser was developed in 1960 and the first medium used was the ruby. In 1968, Mulvaney and Beck reported that although the ruby laser could effectively fragment urinary calculi, it generated excessive heat and was not appropriate for clinical use. This continuous-wave laser simply heats the stone until vaporization occurs, which requires the laser to generate heat greater than the melting point of the stone. A solution for this problem came with the development of pulsed lasers: the application of pulsed energy results in high-power density at the stone's surface but little heat dissipation. The first widely available laser lithotrite was the pulsed-dye laser, which employed a coumarin green dye as the liquid laser medium. Although the coumarin pulsed-dye laser represented a major advancement in intracorporeal lithotripsy, there were a number of significant drawbacks to this technology in that stones of certain composition (calcium oxalate monohydrate, cystine) would not fragment well or even at all, coumarin dye is a toxic agent and required cumbersome disposal procedures, and the required eye protection made visualization of the stone and fiber difficult.

Continued technologic advancements eventually led to the development of the holmium:YAG laser. The holmium laser is a solid-state laser system that operates at a wavelength of 2140 nm in the pulsed mode. Pulse duration of the holmium laser ranges from 250 to 350 microseconds and is substantially longer than the pulse duration in pulsed-dye lasers. The holmium laser is highly absorbed by water; because tissues are composed mainly of water the majority of the holmium laser energy is absorbed superficially, which results in superficial cutting or ablation. The zone of thermal injury associated with laser ablation ranges from 0.5 to 1.0 mm (Wollin and Denstedt, 1998). The mechanism of stone fragmentation of the holmium:YAG laser is different from that of the pulsed-dye lasers. The long holmium:YAG pulse duration produces an elongated cavitation bubble that generates only a weak shock wave, in contrast to the strong shock wave produced by short-pulse lasers. Vassar and associates (1999) demonstrated that during holmium lithotripsy, stone fragmentation began before bubble collapse and shock wave production. Furthermore, no stone fragmentation occurred when the fiber was discharged at an incident angle of 90 degrees. Lithotripsy was more efficient for dry stones in air, indicating that the holmium laser requires direct absorption of laser energy. These data, as well as the presence of thermal products after holmium irradiation, such as glowing hot stone fragments, indicate that holmium laser lithotripsy occurs primarily through a photothermal mechanism that causes stone vaporization (Dushinski and Lingeman, 1998; Wollin and Denstedt, 1998; Vassar et al, 1999).

Advantages and Disadvantages. The holmium:YAG laser can transmit its energy through a flexible fiber, which facilitates intracorporeal lithotripsy throughout the entire collecting system. However, compared with EHL, the holmium:YAG laser is safer and

more efficient. Whereas EHL may cause injury to the ureter even when the probe is activated several millimeters away from the ureteral wall, the holmium laser may be safely activated at a distance of 0.5 to 1 mm from the ureteral wall (Santa-Cruz et al, 1998). **The ability of the holmium laser to fragment all stones regardless of composition is a clear advantage** over the coumarin pulsed-dye laser. Successful fragmentation of ureteral stones of all compositions has been reported, and mean perforation and stricture rates are generally in the range of 1% to 2%. During PNL the holmium laser is most helpful in clearing smaller stones (<2 cm) when the use of flexible instruments is required for access to stones in a calyx remote from the nephrostomy site. **The holmium laser is one of the safest, most effective, and most versatile intracorporeal lithotripters.** Further advantages of the holmium laser include its production of significantly smaller fragments compared with other lithotrites. These small fragments are easily irrigated out of the collecting system, which reduces the need for extraction of the fragments with basket or grasping devices (Teichman et al, 1998a). **The holmium laser produces a weak shock wave, which reduces the likelihood of retropulsion of the stone** or stone fragments compared with EHL or pneumatic lithotrites (Teichman et al, 1998a; Vassar et al, 1999; Sofer and Denstedt, 2000). However, the 365- and 550- μ m laser fibers will cause significantly more retropulsion than the 200- μ m fibers (White et al, 1998). Of note, Kang and associates (2006) demonstrated that not just the laser fiber size, but also laser settings, such as the pulse duration, will affect stone retropulsion. The authors found that stone retropulsion could be significantly reduced by increasing the laser pulse duration.

The holmium laser has several distinct operating advantages compared with the coumarin pulsed-dye laser. The required eye protection for the holmium laser does not compromise the ureteroscopic view of the stone or the fiber (Segura, 1999). In fact, the holmium laser properties are such that with use of energy levels applied for stone disease (i.e., less than 15 W), the operator's cornea would be damaged only if it were positioned at a distance of 10 cm or less from the fiber (Scarpa et al, 1999). The holmium laser is more compact than the coumarin laser, requires minimal maintenance, and is ready for use 1 minute after it is activated.

The major disadvantage of the holmium laser is the initial high cost of the device and the cost of the laser fibers. Elashry and coworkers (1996) noted an advantage of EHL over holmium laser lithotripsy in capital and service contract cost and lithotripter cost per case. However, **the holmium laser has multiple soft tissue applications and can be used to treat patients with benign prostatic hyperplasia, strictures, and urothelial tumors.** In addition, the laser fibers are reusable, so that the effective cost of the holmium laser device and reusable fibers may be lower than that of EHL (Teichman et al, 1998a). The most significant improvement in holmium laser lithotripsy will likely come from improved delivery fibers. At present, the smallest fiber in widespread use, the 200- μ m fiber, impedes deflection of a flexible ureteroscope by up to 20 degrees. As smaller laser fibers, such as those of 150- μ m diameter and smaller, are produced, it is likely that this effect on endoscope deflection will be further reduced. The fracture of a laser fiber inside an endoscope can result in a catastrophic failure of the scope, because when this occurs the fiberoptic bundles that transmit images and light are generally destroyed. Future efforts toward maximizing fiber durability may reduce these events.

The thulium fiber laser has emerged as a potential therapeutic alternative to the holmium laser, because it may hold several advantages over the holmium platform. Its laser fibers are smaller, which may permit improved endoscope deflection and irrigation flow (Blackmon et al, 2010). At present, though, its use in lithotripsy remains investigational.

Technique. The technique of holmium laser lithotripsy is relatively straightforward and involves placement of the fiber on the stone surface before the laser is activated. Clear vision is essential at all times to avoid mucosal perforation. After initiation of holmium laser lithotripsy, a short pause is often required because of the "snowstorm effect" created by the scattering of minute stone fragments, which can be cleared by endoscopic irrigation (Scarpa et al,

1999). Caution must be exercised in operating the holmium laser near a guidewire or a basket because **the holmium laser is capable of cutting through metal** (Freiha et al, 1997; Lane et al, 2005). Furthermore, the laser fiber should extend at least 2 mm beyond the tip of the endoscope to avoid destroying the lens system or the working channel of the endoscope. Baskets used to stabilize calculi during laser lithotripsy should be the preformed type and not the type manufactured by bending of the wire; if they are inadvertently transected by the holmium laser, they will retain the basket shape and not cause a sharp barbed effect (Grasso and Chalikh, 1998).

Holmium laser fibers are available in 200-, 365-, 550-, and 1000- μ m diameters as well as end- or side-firing fibers. However, only the 200- and 365- μ m fibers are used for flexible intracorporeal lithotripsy. Teichman and colleagues (1998b) reported that the 550- μ m side-firing fiber is more effective than the end-firing fiber during PNL, suggesting that the more nearly normal (perpendicular) laser-to-calculus incident angle provided by the side-firing fiber enhances lithotripsy. However, in treatment of ureteral stones, the end-firing fiber may produce a better angle of attack. **Lithotripsy with the holmium laser depends on the pulse energy output and the diameter of the optical delivery fiber, suggesting that lithotripsy efficiency correlates with energy density** (Vassar et al, 1998). Energy density increases with decreasing fiber diameter, although Calvano and associates (1999) demonstrated, in vitro, that peak lithotripsy occurred with 365- and 550- μ m fibers, whereas the 200- μ m fiber can act as a fine drill, which is less effective. Compared with some of the soft tissue applications of the holmium laser, the power used for stone fragmentation is considerably lower. In general, pulse energies of 0.6 to 1.2 J and pulse rates of 5 to 15 Hz are used (Wollin and Denstedt, 1998; Spore et al, 1999). Because high-pulse energy narrows the safety margin and may increase stone retropulsion as well as fiber damage, **it is recommended that treatment be begun with low-pulse energy (e.g., 0.6 J) with a pulse rate of 6 Hz and that pulse frequency be increased (in preference to increasing pulse energy) as needed to speed fragmentation** (Spore et al, 1999). To maximize lithotripsy efficiency, the treating physician should move the laser fiber over the stone surface in a "painting" fashion, vaporizing the stone rather than fragmenting it, and avoid drilling into the stone, fracturing the fiber tip, or drilling past the stone, damaging the urothelium. The laser fiber should be kept at least 1 mm from the urothelium, and lithotripsy should proceed until the stone fragments are small enough to be passed spontaneously or can be safely retrieved with a basket or grasping device.

Stone retropulsion during laser lithotripsy can be advantageous in certain settings. When a stone is positioned in a renal calyx, firing the laser at high frequency will agitate the stone material, bringing the stones or pieces of the stone into rapid close contact with the tip of the laser fiber. Stone fragmentation is enhanced by the increasing likelihood of direct laser contact or contact with other calculus material. This phenomenon has been termed the "popcorn technique," because it bears a semblance to popcorn kernels popping in a heater (Chawla et al, 2008).

Lithotripters

Ballistic Lithotripsy. Ballistic lithotripsy relies on energy generated by the movement of a projectile (Fig. 54-2). The initial movement of the projectile can be induced by a variety of stimuli, but once the projectile is in contact with another object the ballistic energy is transferred to the object. Flexible objects preserve the momentum of the energy, but inflexible objects, such as a stone, fragment on impact (a "jackhammer" effect).

Several manufacturers have introduced ballistic lithotrites. The Swiss LithoClast (Boston Scientific, Natick, MA), introduced in the early 1990s, was the first ballistic lithotrite. The metal projectile in the hand piece of the LithoClast is propelled by measured bursts of compressed air against the head of a metal probe at a frequency of 12 cycles per second. The probe tip is placed against the stone, and the LithoClast is activated by a foot pedal (Denstedt et al, 1992). Rane and associates (2008) first reported on a novel, handheld ballistic lithotripter, the StoneBreaker (Cook Medical, Bloomington,

Figure 54-2. Schematic illustration of the LithoClast (Electromedical Systems, Kaufering, Germany) hand piece mechanism. An oscillating pellet provides ballistic energy to the probe, resulting in a jackhammer-like effect on calculi. (Courtesy Dr. John Denstedt.)

Figure 54-3. Ultrasound lithotripsy generator and hand piece.

IN). This portable device uses a small cylinder-based air supply, rather than hospital air, simplifying its ergonomic profile. Chew and associates (2011) reported a multicenter trial that compared the StoneBreaker with the Swiss LithoClast during PNL, and found that the StoneBreaker was easier to set up and use, and stone fragmentation with it was more rapid. Wang and associates (2012) investigated an alternative hand-held device, the Swiss LithoBreaker (Electro Medical Systems, Nyon, Switzerland), an electrokinetic device. In their in vitro effort, the authors found that although it was efficient in a ureteroscopic model, it performed poorly in a percutaneous model (Wang et al, 2012).

Advantages and Disadvantages. The ballistic lithotrites provide an effective means for stone fragmentation in the entire urinary tract, with a wide margin of safety. Successful fragmentation of ureteral stones of all compositions has been reported in 73% to 100% of cases, a success rate similar to that of EHL. The lower success rate of 73.7% reported by Knispel and associates (1998) suggests reduced efficiency of the LithoClast when it is applied through the deflected working channel (30 degrees) of the 6.9-Fr semirigid ureteroscope. As well, a significant decrease in the maximum tip displacement and velocity of the LithoClast 0.89-mm flexible probe occurs when it is used through a flexible ureteroscope deflected more than 24 degrees (Zhu et al, 2000). Grocela and Dretler (1997) also reported that for the current ballistic devices, bowing of the probe during lithotripsy results in significant power loss. Ballistic devices may be especially advantageous when large or hard stones are encountered during PNL or endoscopic lithotripsy of bladder calculi. In contrast to ureteral stones, kidney stones are easily "pinned down" against the urothelium during ballistic lithotripsy, allowing a rapid and more efficient fragmentation method than ultrasonic lithotripsy. Once the bulk of the calculus is fragmented, lithotripsy can be completed with the ultrasonic lithotripter, which can also aspirate minute stone fragments (Denstedt, 1993; Teh et al, 1998; Yavasoglu et al, 1999). Compared with EHL, ultrasonic lithotripsy, and laser lithotripsy, ballistic devices have a significantly lower risk for ureteral perforation (Piergiorganni et al, 1994). In an animal model, despite 6 minutes of activation in direct contact with the ureteral wall, a ballistic lithotripter was unable to cause perforation (Santa-Cruz et al, 1998). Furthermore, because no heat is produced during lithotripsy, the risk for thermal injury to the urothelium is eliminated.

One of the advantages of ballistic lithotrites is their relatively low cost and low maintenance. Although the devices are more expensive than EHL, in terms of capital equipment purchasing, there are no disposable costs and the probes have an extremely long life span (Hofbauer et al, 1995).

Disadvantages of ballistic devices include the rigid nature of the technology, which requires ureteroscopes or nephroscopes with straight working channels. In addition, ballistic lithotripsy is associated with a relatively high rate of stone retropulsion, reported in 2% to 17% of ureteral stone treatments. Often, failure to fragment a stone is related to an inability to trap a ureteral stone in a capacious ureter (Denstedt et al, 1992). The migration rate depends on the initial stone location; there is a higher chance of stone migration for proximal ureteral stones compared with distal ureteral

stones (Knispel et al, 1998). Limited data are available on the beneficial effects of suction devices, such as the LithoVac (Boston Scientific), in limiting stone migration. Delvecchio and colleagues (2003) reported the use of the 0.8-mm pneumatic lithotripsy probe placed through a 4.8-Fr hollow LithoVac suction probe in 21 patients with ureteral stones. Overall stone-free rate at 3 months was 95%, and the suction device reportedly facilitated lithotripsy by preventing stone migration and maintaining a clear endoscopic view.

Teichman and associates (1998a) reported that fragments larger than 4 mm are produced by all types of endoscopic lithotrites, with the exception of the holmium:YAG laser. Fragmenting a stone into pieces smaller than 4 mm with a ballistic lithotripter can be challenging, especially a hard stone in a dilated ureter. Fragments larger than 4 mm are associated with a higher rate of repeated ureteroscopy and therefore should be removed with baskets or stone graspers during the initial procedure (Keeley et al, 1999).

Technique. Like other lithotrites, the ballistic lithotripter should be activated only when there is a clear view of the stone and the probe position can be identified. Fixation of the stone is rarely difficult in the kidney or the bladder but may be a problem in the ureter. Fixation of ureteral stones with a basket or proximal placement of a ureteral occlusion device is sometimes necessary (Ursiny and Eisner, 2013). The goal of ballistic lithotripsy in the ureter is to generate fragments that are small enough to permit spontaneous passage (<2 mm). However, more often, larger fragments have to be removed with a basket or grasping device. The relatively atraumatic nature of ballistic lithotripsy may allow the avoidance of stent placement after ureteroscopy. Tan and colleagues (1998) reported the use of a stent in only 9 of 68 patients undergoing ballistic lithotripsy. In this series, difficult ureteral access and severe edema and trauma at the site of stone impaction were indications for stent placement.

Ultrasonic Lithotripsy. Mulvaney (1953) first reported the use of ultrasonic vibrations to break renal calculi in 1953. Since then, ultrasonic lithotripsy has become a commonly used modality for the treatment of renal calculi during PNL and for the fragmentation of bladder and ureteral stones. The ultrasound probe works by applying electrical energy to excite a piezoceramic plate in the ultrasound transducer (Fig. 54-3). The plate resonates at a specific frequency and generates ultrasonic waves at a frequency of 23,000 to 25,000 Hz. At operating frequencies there is no audible sound, although 98 dB of ultrasonic inaudible noise levels has been measured (Segura and LeRoy, 1984).

Ultrasound energy is transformed into longitudinal and transverse vibrations of the hollow steel probe, which then transmits the energy to the calculus. The probe tip causes the stone to resonate at high frequency and to break; but when the probe is placed on compliant tissue, such as urothelium, damage is minimal because the tissue does not resonate with the vibrational energy (Grocela and Dretler, 1997). Although some heat may develop at the end of the probe during lithotripsy, with an irrigation rate of 30 mL/min the temperature increase at the tip of the probe can be reduced to a maximum of 1.4°C (Marberger, 1983). Because irrigation may be limited during ureteroscopy, ultrasonic lithotripsy is more efficient during PNL, owing to the greater flow of irrigant through the larger diameter ultrasonic probes that can be used. The

ultrasonic lithotripter system is connected to suction so that debris from the stone is removed continuously with the irrigating fluid during lithotripsy. In addition, the flow of fluid through the hollow probe serves to cool the instrument. Heating of the ultrasound transducer should alert the surgeon to possible occlusion in the probe lumen, an occurrence more commonly encountered with small-diameter probes that are used in the ureter. Although many manufacturers provide an integrated power and suction foot switch for the ultrasonic unit, wall suction with intermittent clamping of the suction tubing by an assistant is a simple and inexpensive alternative. In general, suction is applied only when the ultrasonic lithotripter is activated, and suction pressures in the range of 60 to 80 cm H₂O are sufficient to maintain adequate flow of irrigant during lithotripsy. Higher suction pressures tend to draw air bubbles into the system, impeding vision. Ultrasonic probes are available at sizes ranging from 2.5 to 12 Fr. The 2.5-Fr probe is solid and contains no hollow center for suction. Therefore, when it is used in the ureter, heat dissipation is slow. Bending the probe results in energy loss at the convexity of the bend, with the energy being transformed to heat (Marberger, 1983).

Stones vary in their susceptibility to destruction with ultrasound. Although the chemical composition of the stone influences the time required for complete disintegration (cystine, calcium oxalate monohydrate, and uric acid being the most resistant to fragmentation), the size, density, and surface structure of the calculus appear to be more important. Smaller stones are more rapidly destroyed, as are rough stones. Smooth-surfaced large stones may be more difficult to fragment (Marberger, 1983; Segura and LeRoy, 1984).

Advantages and Disadvantages. The major advantage of ultrasonic lithotripsy is the efficient combination of stone fragmentation and simultaneous fragment removal. Fragments smaller than 2 mm are aspirated through the hollow lithotrite along with the irrigation fluid. Larger fragments may be removed with forceps or baskets. The efficiency of this technique coupled with the minimal risk for serious tissue damage has made this technology popular. Ultrasonic lithotripsy is often the first modality used for stone fragmentation during PNL.

However, the rigid nature of ultrasonic probes and their small diameter limit the appeal of this technology in treatment of ureteral stones. A ureteroscope with a straight working channel is required. Furthermore, a relatively large 5-Fr working channel is needed to accommodate the 4.5-Fr hollow probe. However, success rates between 69% and 100% have been reported (Denstedt, 1996; Gur et al, 2004). The technology may be particularly useful for patients with large ureteral stones as well as for those with steinstrasse because removal of stone debris is facilitated. Excellent results also have been reported for distal ureteral stones easily accessible to the rigid ureteroscope (Grocera and Dretler, 1997; Segura, 1999). Chaussy and colleagues (1987) reported a 96.6% complete fragmentation rate in 118 patients with a 2.5-Fr solid probe that can be used with smaller ureteroscopes, and Fuchs (1988) reported similar results. However, in a later report, Murthy and associates (1997) compared a group of 25 patients treated by a rigid ureteroscope and the 3-Fr ultrasonic solid probe with a group of 122 patients treated by the LithoClast ballistic device, and the overall success rate was significantly higher for the LithoClast group than for the ultrasonic group (97.3% vs. 84%, respectively).

Technique. When ultrasonic lithotripsy is applied during PNL the stone should first be trapped between the probe and the urothelium. The application of gentle pressure to the stone enhances fragmentation, but the temptation to push too hard should be avoided because calculi can easily be pushed through the urothelium. The risk for perforation increases with smaller or more rugedly surfaced stones because the force applied to the stone is transferred to a smaller surface area of the urothelium. The risk for perforation is particularly high in the thin-walled renal pelvis or ureter rather than in a calyx that is backed by renal parenchyma.

When ureteral stones are treated the ureter may need to be dilated to allow passage of the offset rigid ureteroscope. The ultrasonic probe is passed through the working channel and placed directly on the stone. If necessary, the stone can be engaged in a

stone basket to prevent proximal migration. As with other intracorporeal lithotripsy devices the goal of treatment is either to fragment the stone completely or to generate fragments that are small enough to be extracted or passed spontaneously.

Combination Ballistic and Ultrasonic Devices

Several manufacturers have introduced combined ultrasonic and pneumatic devices that aim to combine the superior fragmentation ability of the pneumatic component with the ability of the ultrasonic modality to simultaneously evacuate stone fragments. The first combination device brought to the clinical market was the LithoClast Ultra, which relied on a combination hand piece (actually, two separate hand pieces connected together) to join the ultrasonic and pneumatic components. The first portion of the combination hand piece was a traditionally designed pneumatic handle, with a smaller diameter solid probe. The ultrasonic handle, driven by a standard piezoelectric mechanism, was modified to allow the coaxial insertion of the pneumatic probe. Each modality can be activated separately or in unison; when operated in unison, the ballistic fragmentation of the stone is accomplished with the pneumatic component and the ultrasonic component then removes the resulting debris.

Given the varied types of rigid intracorporeal devices (stand-alone ballistic and ultrasonic as well as combination ballistic and ultrasonic), a rigorous and impartial evaluation of intracorporeal lithotripters is a subject of importance to urologists. Each device may have certain unique properties that make it more suitable for particular applications, and manufacturer's claims may contain elements of bias that make it difficult for the urologist to ascertain which device may be most suitable to purchase. Therefore a number of investigators have devised testing methods to compare intracorporeal lithotrites. Liatsikos and associates (2001) first reported an in vitro testing system designed to measure the efficiency of ultrasonic lithotrites in which stone phantoms were fragmented in a nephroscope-guided manner. The inherent weakness in this study design was that stone fragmentation was directed by hand, which could introduce significant operator bias. Haupt and Haupt (2003) subsequently reported an in vitro system that relied on an elaborate weight and fulcrum to bring a stone phantom into contact with the probe tip at a constant force. Although operator bias was no longer present, this system was complex and cumbersome, making replication challenging. Kuo and associates (2003b) have presented a novel and simple hands-free testing system in which the ultrasonic hand pieces were secured upright and the stone phantom placed into contact with the probe by a weight mechanism (Fig. 54-4). This design system was first used to test the efficiency of pure ultrasonic lithotrites and measured the time it took for the probe to penetrate the stone phantom. In this study the Olympus LUS-2 (Olympus, Melville, NY) produced the fastest overall stone penetration time.

After the introduction of the combination ultrasonic and pneumatic devices, the same testing apparatus previously used by Kuo and associates (2004) to evaluate the ultrasonic devices was used to evaluate the LithoClast Ultra. Because of the wide variety of ultrasonic power and pneumatic frequency settings available, the testing apparatus was used to assess the efficiency of various setting combinations. The end point was stone penetration time, and the fastest stone penetration times were achieved at settings of 100% ultrasonic power and 12-Hz pneumatic frequency. Pietrow and associates (2003) evaluated the efficiency of the LithoClast Ultra combination device in a clinical setting, performing a prospective, randomized trial comparing the combination device with standard ultrasonic lithotrites in patients undergoing PNL. The stone clearance times were significantly better for the combination device than for the conventional ultrasonic lithotripters.

The CyberWand (Gyrus ACMI, Southborough, MA) is an intracorporeal lithotripter that relies on a dual ultrasonic probe design that incorporates coaxial high-frequency and low-frequency probes. The dual probe design creates a synergistic effect, which enables efficient stone fragmentation while still allowing the suction evacuation of small fragments in the same way as other ultrasonic devices.

Figure 54-4. In vitro testing apparatus for a “hands-free” testing approach to the evaluation of intracorporeal lithotrites.

Kim and associates (2007) used the previously mentioned hands-free testing design previously described by Kuo and associates (2003a) to find that the stone penetration time for the CyberWand was almost twice as rapid as it was for the LithoClast Ultra.

Krambeck and associates (2011) reported a multicenter trial comparing the CyberWand with a conventional ultrasonic device (Olympus LUS-II) and found that there was no appreciable difference in stone fragmentation rates or complications between the two devices. Chu and associates (2013) also investigated whether pneumatic, ultrasonic, or combination devices had an effect on postoperative fever; in a study of over 5000 patients collated through the Clinical Research Office of the Endourological Society, they found that the lithotrite had no effect (Chu et al, 2013).

Conclusion

The current technology of intracorporeal lithotripsy provides the urologist with several effective options for stone fragmentation, depending on the type of endoscope used (rigid or flexible) and the location and accessibility of the stone. The holmium laser has become the mainstay of ureterorenoscopic lithotripsy by virtue of its ability to fragment all stones. As well, the use of small-diameter fibers allows access to all areas of the ureter and intrarenal collecting system. However, for patients with complex, large-volume calculi undergoing PNL, the combination devices will permit more efficient fragmentation of the stone. When selecting a lithotripter for purchase, the institution must take into account the number and nature of stone-related procedures performed to maximize the utility and cost-effectiveness of the device.

Extracorporeal Shock wave Lithotripsy

Methods and Physical Principles

In extracorporeal SWL a source external to the patient's body generates a shock wave. Specifically, the energy source rapidly deposits

Figure 54-5. Schematic view of an electrohydraulic shock wave generator. An electrode is used to generate a shock wave. F1, focus 1; F2, focus 2.

pulses of energy into a fluid environment, which results in the generation of a shock wave. Shock waves are surfaces that divide material ahead, not yet affected by the disturbance, from that behind, which has been compressed as a consequence of energy input at the source (Sturtevant, 1996). These waves move faster than the speed of sound, and the stronger the initial shock, the faster the shock wave moves. Their behavior is characteristic of the propagation of nonlinear waves. Although the shock waves in lithotripters generate large pressures, they are relatively weak in that they induce only slight compression and deformation of a material. The uniqueness of the shock wave lithotripter is in its exploitation of shock wave focusing. Relatively weak, noninvasive waves are generated externally and transmitted through the body. The shock waves build to sufficient strength only at the target, where they generate enough force to fragment a stone.

Generator Type. The three primary types of shock wave generators are electrohydraulic (spark gap), electromagnetic, and piezoelectric.

Electrohydraulic (Spark Gap) Generator. In the electrohydraulic shock wave lithotripter, a spherically expanding shock wave is generated by an underwater spark discharge (Cleveland et al, 2000). High voltage is applied to two opposing electrodes positioned about 1 mm apart. The high-voltage spark discharge causes the explosive vaporization of water at the electrode tip. For the spherically expanding shock wave to be focused on a calculus the electrode is placed at one focus (termed F1) of an ellipsoid and the target (the kidney stone) is placed at the other focus (termed F2). Figure 54-5 shows a hemiellipsoid reflector and a spark gap typical of those used in the older electrohydraulic machines. This arrangement allows the projection of the majority of the original shock wave energy from the electrode tip to the stone, provided the electrode tip is precisely at F1. The body of the electrode varies in orientation among machines in that it is positioned within the ellipsoid to provide an easy means of replacement as it deteriorates.

The clear advantage of this generator is its effectiveness in breaking kidney stones (Lingeman, 1997). Disadvantages are the

substantial pressure fluctuations from shock to shock and a relatively short electrode life. New, longer life electrodes (like the NewTrode by HMT, Lengwil, Switzerland) have been developed to overcome these drawbacks. Another issue to consider is that as the electrode deteriorates, it wears down, and a 1-mm displacement of the electrode tip off F1 can shift F2 up to 1 cm off the initial target.

Electromagnetic Generator. Whereas the electrohydraulic lithotripter produces focused shock waves by bouncing spherically expanding shocks off an ellipsoid reflector, the electromagnetic generators produce either plane or cylindrical shock waves. The plane waves are focused by an acoustic lens (Fig. 54-6); the cylindrical waves are reflected by a parabolic reflector (Fig. 54-7) and trans-

Figure 54-6. Schematic view of an electromagnetic shock wave generator that uses an acoustic lens to focus the shock wave. An electromagnetic coil is used to generate the shock wave. F2, focus 2.

Figure 54-7. Schematic view of an electromagnetic shock wave generator that uses a parabolic reflector to focus the shock wave. An electromagnetic coil is used to generate the shock wave. F2, focus 2.

formed into a spherical wave. The basic design of an electromagnetic generator is simple. Figure 54-6 shows a system that uses a water-filled shock tube containing two conducting cylindrical plates separated by a thin insulating sheet. When an electrical current is sent through one or both of the conductors, a strong magnetic field is produced between the conductors, moving the plate against the water and thereby generating a pressure wave. The electromagnetic force that is generated, termed *magnetic pressure*, causes a corresponding pressure (shock wave) in the water. The shock front produced is a plane wave that is of the same diameter as the current-carrying plates. The energy in the shock wave is concentrated onto the target by focusing it with an acoustic lens. The electromagnetic system that uses a cylindrical source (see Fig. 54-7) also has a cylindrical coil surrounded by a cylindrical membrane that is pushed away from the coil by the induction of a magnetic field between the two components. In both systems the pressure pulse has only one focal point (F2) that is positioned on the target.

Electromagnetic generators are more controllable and reproducible than electrohydraulic generators because they do not incorporate a variable in their design such as the underwater spark discharge. Other advantages include the introduction of energy into the patient's body over a large skin area, which may cause less pain. In addition, a small focal point can be achieved with high-energy densities, which may increase its effectiveness in breaking stones. This generator will deliver several hundred thousand shock waves before servicing, thereby eliminating the need for frequent electrode replacement, which is required with most electrohydraulic machines. A disadvantage of this design may be that the small focal region of high energy results in an increased rate of subcapsular hematoma formation. The rate of subcapsular hematoma formation for the Storz Modulith (Storz Medical, Tägerwil, Switzerland) has been suggested to be 3.1% to 3.7% (Dhar et al, 2004). Piper and associates (2001) suggested that perinephric hematomas may occur in up to 12% of patients treated with a DoLi S lithotripter (Dornier Medical Systems, Kennesaw, GA). In contrast, perinephric hematomas were reported to occur in approximately 0.6% of patients undergoing SWL with the unmodified Dornier HM3 machine (Chaussy and Schmiedt, 1984; Knapp et al, 1987).

Piezoelectric Generator. The piezoelectric lithotripter also produces plane shock waves with directly converging shockfronts. These generators are made of a mosaic of small, polarized, polycrystalline, ceramic elements (barium titanate), each of which can be induced to rapidly expand by the application of a high-voltage pulse (Fig. 54-8). Owing to the limited power of a single piezoelectric element, 300 to 3000 crystals are necessary for the generation of a sufficiently large shock pressure. The piezoelectric elements are usually placed on the inside of a spherical dish to permit convergence of the shockfront. The focus of the system is at the geometric center of the spherical dish.

The advantages of this generator include the focusing accuracy, a long service life, and the possibility of an anesthetic-free treatment because of the relatively low-energy density at the skin entry point of the shock wave. For this reason, piezoelectric lithotripters in general tend to produce less discomfort than do lithotripters with other energy sources. A major disadvantage of this system is the insufficient power it delivers, which hampers its ability to effectively break renal stones. The piezoelectric energy sources produce some of the highest peak pressures of any lithotripter, but the actual energy delivered to the stone per shock wave pulse is several orders of magnitude lower than that delivered by an electrohydraulic machine because of the extremely tiny volume of F2.

Other Generators. Microexplosive generators have also been produced but have not gained widespread acceptance. The explosion of tiny lead azide pellets within a parabolic reflector generates the device's shock wave (Kuwahara et al, 1987). Despite the effectiveness of this type of generator in producing shock waves, this technology has not met with commercial success because of concerns about the storage and handling of the volatile lead azide pellets. Still other methods of shock wave generation use a laser beam or a

Figure 54-8. Schematic view of a piezoelectric shock wave generator. Numerous polarized polycrystalline ceramic elements are positioned on the inside of a spherical dish. F2, focus 2.

multistage light gas gun, but these too have not been well received commercially.

Focused ultrasound has emerged as a technology that can expel small stones or stone fragments from the urinary system (Sorensen et al, 2013). Harper and associates (2013) reported an in vitro study that effectively and rapidly migrated stone material through a urinary system phantom. Although the technology is not yet clinically available, it may ultimately play a role in extracorporeal stone management.

Imaging Systems. There are three basic designs used by lithotripter manufacturers for stone localization. They are fluoroscopy alone, ultrasonography alone, and the combination of ultrasonography and fluoroscopy.

Fluoroscopy Alone. The original Dornier HM3 lithotripter used two x-ray converters arranged at oblique angles to the patient and 90 degrees from each other to localize the stone effectively at F2. To reduce the cost of lithotripters, an adjustable C-arm has been subsequently introduced on many devices. There is presently a remarkable similarity in the fluoroscopic systems used among manufacturers. This appears to be primarily the result of a common theme in the industry to develop multifunctional tables around these machines. The fluoroscopic system typically consists of a high-quality digitized x-ray imaging system mounted on a rotatable C-arm with an isocentrically integrated shock wave source. Because the shock wave head can be rotated out of the field of the fluoroscopic system, the table can be used for routine urologic fluoroscopic applications.

The primary advantages of fluoroscopy still include its familiarity to most urologists, the ability to visualize radiopaque calculi throughout the urinary tract, the ability to use iodinated contrast agents to aid in stone localization, and the ability to display anatomic detail. The disadvantages include the exposure of the staff and patient to ionizing radiation, the high maintenance demands of the equipment, and the inability to visualize radiolucent calculi without the use of radiographic contrast agents.

Ultrasonography Alone. Ultrasonic localization was initially designed to aid multifunctional lithotripters for treatment of both urinary and biliary stones. It is presently used in several low-cost machines because it is inexpensive to manufacture and maintain compared with fluoroscopic systems. Another major advantage of this technology is in the treatment of children and infants when concern exists about the dose of ionizing radiation. In addition, ultrasonography can localize slightly opaque or nonopaque calculi.

Despite its advantages, ultrasound imaging has a number of significant disadvantages. Sonographic localization of a kidney stone requires a highly trained operator. Complicating the issue of stone detection is the fact that it is almost impossible to view a kidney stone in areas such as the middle third of the ureter or when there is an indwelling ureteral catheter. Once a stone is fragmented,

it is difficult to identify each individual stone piece. Unfortunately, these disadvantages tend to overshadow the advantages of ultrasound imaging.

Combination of Ultrasonography and Fluoroscopy. As the demand for interdisciplinary lithotripters has increased, the lithotripsy industry has responded, in some cases combining ultrasonography and fluoroscopy for stone localization. There are clearly advantages to these setups, but each system has a drawback that limits one of the functions of the system.

Anesthesia. The approach to anesthesia for lithotripsy has changed considerably since clinical SWL began in 1980. At that time, regional or general anesthesia was used in all instances because the unmodified HM3 device (15.6-cm ellipsoid; 80-nF generator) produced a powerful shock wave and treatment at recommended energy levels caused intolerable pain. Subsequently, urologists and lithotripter manufacturers recognized that the HM3 is considerably more powerful at the recommended energy setting than is necessary for the fragmentation of most renal calculi, an observation that spawned interest in less powerful lithotripters with lessened anesthesia requirements (Wilbert et al, 1987; Marberger et al, 1988). Several researchers have noted that the original HM3 lithotripter without modification produces excellent clinical results when it is used at lower energy settings (Pettersson et al, 1989; Tiselius, 1991; Tolley et al, 1991). In addition, such settings create a smaller lesion at F2 in experimental animals (Connors et al, 2000).

The discomfort experienced during SWL is related directly to the energy density of the shock wave as it passes through the skin and the size of the focal point. In the past decade several new and useful anesthetic techniques adaptable to SWL have been produced that were not available at the time SWL was introduced and include short-acting parenteral sedative-narcotics and topical agents.

Short-acting agents, such as the narcotic alfentanil and the sedative-hypnotics midazolam and propofol, have been used in various combinations to allow most SWL treatments with any lithotripter (including the unmodified Dornier HM3) to be accomplished comfortably for the patient without the need for general or regional anesthesia. Monk and associates (1991) compared two sedative-analgesic techniques (midazolam-alfentanil vs. fentanyl-propofol) and found that both techniques provided adequate anesthesia for SWL with use of an unmodified Dornier HM3 lithotripter. Anesthesia and recovery times were significantly shorter than those recorded for epidural anesthesia techniques. These findings have been confirmed by others (Nelson et al, 2001; Burmeister et al, 2002; Ozcan et al, 2002).

Another approach to minimize anesthesia requirements during SWL has been the use of topical agents. EMLA cream, a eutectic mixture of lidocaine and prilocaine, has been shown significantly to reduce anesthesia requirements during SWL (Basar et al, 2003).

A topical agent, EMLA cream should be applied at least 45 minutes before SWL. The combination of topical agents and short-acting intravenous agents is likely to minimize the amount of these agents required and to shorten recovery times.

Calculi composed of cystine, calcium oxalate monohydrate, or brushite are known to be resistant to fragmentation; if their presence is anticipated, delivery of higher levels of shock wave energy with attendant increased anesthesia requirements should be expected (Dretler, 1988; Klee et al, 1991). Thin patients have more pain during SWL because the converging shock wave is more concentrated at the point of skin penetration. Children and extremely anxious individuals may be served best by general anesthesia. If a lengthy treatment session is anticipated (i.e., bilateral SWL or treatment of ureteral and renal stones), the larger amount of topical and intravenous agents required lessens their appeal.

One important observation regarding the issue of general anesthesia versus intravenous sedation was reported by Sorensen and colleagues (2002) and Eichel and colleagues (2001). In a comparison of patients treated with the DoLi 50 lithotripter, the patients who received general anesthesia experienced a significantly greater stone-free rate than did the patients who underwent intravenous sedation. One possible explanation for this finding is the more controlled respiratory excursion that is conferred by the general anesthetic.

Lithotripter Comparisons

Shock wave lithotripters are considered by the U.S. Food and Drug Administration to be Class II devices. For a lithotripter to be brought to market simply requires documentation that the device has the same intended use and the same technologic characteristics as a predicate device that has already been approved and brought to market. Specific testing that evaluates, in a proscribed manner, the lithotripter's treatment efficacy and safety is not required. Largely as a consequence of this practice, few, if any, appropriately designed comparative trials of lithotripters exist in the published literature. In addition, there are no validated standards within the litho-

tripsy industry regarding a method of quantification of the power and efficiency of lithotripters, a problem further compounded by a lack of knowledge of the number of shock waves that can be safely administered to a kidney during any single SWL session with any lithotripter. Although there is general consensus that re-treatment rates are an appropriate indicator of lithotripter effectiveness, the lack of clinical agreement about the appropriate outcome of lithotripsy (i.e., stone free vs. residual fragments of various size) further hampers comparisons of lithotripters.

Only a small part of the literature published to date on the outcomes of SWL presents data that are stratified sufficiently to permit a meaningful comparative analysis. Surprisingly, despite the proliferation of lithotripters and the variety of solutions devised for stone targeting and shock wave delivery, no other lithotripter system has convincingly equaled or surpassed the results produced by the unmodified Dornier HM3 device. That the most effective lithotripter was invented first is a remarkable achievement for Dornier. In general, the less powerful lithotripters with smaller focal points result in lower stone-free rates or higher re-treatment rates. Additionally, it is now recognized that SWL inflicts a trauma similar to a renal contusion, which occasionally can result in adverse clinical sequelae. Potential concerns about the long-term effects of lithotripsy with the unmodified Dornier HM3 device may have been one motivating factor in the trend within the lithotripsy industry toward, at first, lower power but eventually higher power lithotripters with smaller focal points, with the goal that the efficacy of lithotripsy could be maintained while producing fewer deleterious effects on renal tissue (Figs. 54-9 and 54-10). Unfortunately, the newer lithotripters are less efficacious than the original Dornier device, and no published information is available to suggest that newer lithotripters produce fewer adverse effects for equivalent degrees of efficacy.

Mechanisms of Stone Comminution

Present knowledge in the field of SWL suggests that comminution of a renal stone in a lithotripter field is the consequence of

Figure 54-9. Comparison of the peak amplitude and size of the focal volume of nine different lithotripters. The general trend (from left to right) is a decrease in the device focal volume and an increase in the peak positive pressure. At the far left is the Xi Xin/Eisenmenger lithotripter, a new design that goes against the trend with a diminished peak amplitude and enlarged focal area. F2, focus 2.

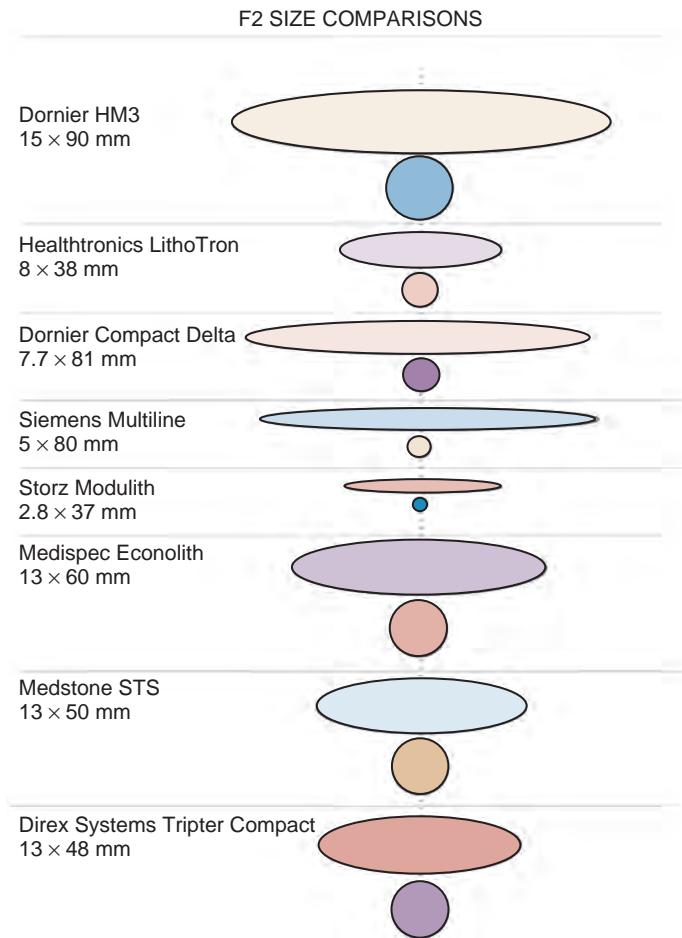

Figure 54-10. Comparison of the focal zones of selected clinical lithotripters showing their dimensions along the axis of the lithotripter (ellipses) and in the focal plane at the focus (circles). F2, focus 2.

failure of the stone material because of the mechanical stresses produced either directly by the incident shock wave or indirectly by the collapse of cavitation bubbles. These events could be occurring simultaneously or separately at the surface of the stone or within the interior of the stone (Fig. 54-11). Several potential mechanisms for SWL stone breakage have been described: spall fracture, squeezing, shear stress, superfocusing, acoustic cavitation, and dynamic fatigue.

Before each of these mechanisms is discussed, consideration of the typical shock wave profile is required. A typical pressure pulse generated by an electrohydraulic shock wave lithotripter is shown in Figure 54-12. It involves an initial short and steep compressive front with pressures of approximately 40 megapascals (MPa) that is followed by a longer, lower amplitude negative (tensile) pressure of 10 MPa, with the entire pulse lasting for a duration of 4 microseconds. Note that the ratio of the positive to negative peak pressures is approximately 5:1. Pressure measurements near the focal region of a Dornier unmodified HM3 indicate a 6-dB beam, of a width of approximately 15 mm. Because kidney stones are also generally of this dimension, the wavefront incident on the stone can be considered a plane wave (Müller, 1990; Cleveland et al, 2000).

The first mechanism by which a stone might break is through **spall fracture**. Once the shock wave enters the stone it will be reflected at sites of impedance mismatch. One such location is at the distal surface of the stone at the stone-fluid (urine) interface (although there could be other internal sites, such as cavities in the stone and interfaces of crystalline and matrix materials). As the shock wave is reflected, it is inverted in phase to a tensile (negative) wave. If the tensile wave exceeds the tensile strength of the stone,

Figure 54-11. Summary of how the various mechanical forces generated by a lithotripsy shock wave might cause a kidney stone to fracture. (Reproduced with permission from Dr. Bradley Sturtevant.)

there is an induction of nucleation and growth of microcracks that eventually coalesce, resulting in stone fragmentation, which is termed **spallation**. The failure plane is located perpendicular to the applied tensile stress. This mechanism is thought to be of considerable importance in that kidney stones, like most brittle materials, will be much more likely to fail under tension rather than compression (Johrde and Cocks, 1985). Lokhandwalla and Sturtevant (2000) suggest that the trailing negative pressure of the lithotripter pulse also exerts tensile stresses of an order of magnitude similar to that of the spall mechanism. Contributing factors to the effectiveness of spallation in generating stone breakage appear to be the size and the shape of the stone as well as its physical properties (i.e., fracture toughness, acoustic speed, density, void dimensions). More spherically shaped stones may focus the tensile wave after reflection and thus further increase the tensile stress. Stones with larger diameters may allow sufficient tensile stress to be generated so that the tensile strength of the stone can be exceeded more easily. If these factors are important, then smaller, irregularly shaped stones may not fracture by spallation.

Eisenmenger (1998) first suggested that the **second mechanism for stone breakage, termed squeezing-splitting or circumferential compression**, occurs because of the difference in sound speed between the stone and the surrounding fluid. The shock wave inside the stone advances faster through the stone than the shock wave propagating in the fluid outside the stone. The shock wave

Figure 54-12. A typical pressure pulse at the lithotripter focus (F2) as measured by a polyvinylidene difluoride membrane hydrophone. First, there is a steep positive pressure front of about 40 MPa, which is followed by a negative pressure of 10 MPa, with the entire pulse lasting for a duration of 4 μ sec. (From Coleman AJ, Saunders JE, Preston RC, et al. Pressure waveforms generated by a Dornier extracorporeal shock wave lithotripter. *Ultrasound Med Biol* 1987;13: 651-7.)

that propagates in the fluid outside the stone thus produces a circumferential force on the stone, resulting in a tensile stress in the stone that is at its maximum at the proximal and distal ends of the stone. The resulting squeezing force could split the stone either in a plane parallel to the shock wave propagation direction or, depending on the elastic properties of the stone, possibly in a plane parallel to the shock wave front. It has been theorized that squeezing should be enhanced when the entire stone falls within the diameter of the focal zone. Thus current third-generation lithotripters that have very small focal zones will not make use of this mechanism, because the stone size is typically greater than the focal zone, whereas the original Dornier HM3 machine would.

The third mechanism is shear stress. Shear stress will be generated by shear waves (also termed *transverse waves*) that develop as the shock wave passes into the stone. The shear waves propagate through the stone and will result in regions of high shear stress inside the stone. In contrast to compression waves, which move the molecules in the direction of propagation, a shear wave results in translation of molecules transverse to the direction of propagation, and therefore the molecules are not compressed but are shifted sideways by the wave. Many materials are weak in shear, particularly if they consist of layers, because the bonding strength of the matrix between layers often has a low ultimate shear stress. Calcium oxalate stones commonly possess alternating layers of mineral and matrix, and the shear stress induced by the transverse wave could cause such stones to fail. Theoretical work by Sapozhnikov and colleagues (2003) suggests that the shear wave mechanism will lead to a tensile strain in cylindrical stones that is 5 to 10 times larger than that induced by spall. They also suggest that cracks will be initiated in the center of the stone and grow in a direction perpendicular to the axis of the stone.

The fourth mechanism for stone breakage, *superfocusing*, is the amplification of stresses inside the stone because of the geometry of that stone. The shock wave that is reflected at the distal surface of the stone can be focused by either refraction or diffraction from the corners of the stone. Several groups have demonstrated that these reflected waves can be focused to regions of high stress in the interior of the stone and that this can lead to failure (Gracowski et al, 1993; Xi and Zhong, 2001). The regions of high stress (both tensile and shear) depend on the geometry of the stone as well as its elastic properties.

The fifth potential mechanism for SWL stone breakage is *cavitation* (Coleman et al, 1987; Crum, 1988; Vakil and Everbach,

1993; Zhong and Chuong, 1993; Zhong et al, 1993). Cavitation is defined as the formation and subsequent dynamic behavior of bubbles. The lithotripter-generated pressure field has been found to induce cavitation in both in vitro and in vivo studies. The negative pressure in the trailing part of the pulse causes bubbles to grow at nucleation sites. A nucleation site is an inhomogeneity in the fluid, which leads to preferential formation of free gas under stress. During the negative pressure wave, the pressure inside the bubble falls below the vapor pressure of the fluid, and the bubble fills with vapor and grows rapidly in size (almost three orders of magnitude). As these bubbles grow, they oscillate in size for about 200 microseconds and then collapse violently, giving rise to high pressures and temperatures. In the absence of any boundaries, a cavitation bubble remains spherical during collapse, releasing energy primarily by sound radiation, the majority of which is in the form of a shock wave (see Fig. 54-12). This shock wave generates a positive and negative wave and therefore can induce all of the fragmentation mechanisms described in the preceding section. However, in the presence of a boundary, a liquid jet, also termed a *cavitation microjet*, forms inside the bubble during the collapse (Crum, 1979, 1988). This jet can accelerate to extremely high speeds because it converts most of its kinetic energy from the collapse of the cavity interface to the jet itself. The typical bubble radii found in SWL vary from 1 μ m to 1 mm, and bubble jet velocities range from 22 m/sec to 800 m/sec. In actual jet-impact cases the duration of the pressure pulse is only a few microseconds, and, in most instances, the peak pressure lasts for only approximately 1 microsecond. If the liquid jet is near the surface of a stone, it creates a locally compressive stress field in the stone, which propagates spherically into the stone interior.

Numerous investigators have exposed either aluminum foil or brass plates to the focused shock wave generated by a Dornier HM3 machine and observed significant microjet damage (pitting) on the surfaces of these metals. If this event occurs at the surface of a kidney stone, erosion of this surface would be expected; Averkiou and Crum (1996) reported this event for SWL-treated plaster of Paris target stones. To determine if cavitation is the primary mechanism of stone fragmentation, investigators have developed in vitro systems that would eliminate or damp cavitation events. Such systems have included a viscous medium that possesses a much lower number of nucleation sites and a chamber that allows increasing of the ambient pressure that surrounds the growing cavitation bubbles (Vakil et al, 1991; Delius, 1997; Stonehill et al, 1998). These in vitro systems have shown reduced stone damage along with a reduction in cavitation activity. Work by Bailey and associates (1998, 1999), in which the positive and negative waves were inverted with a pressure release reflector, also showed a reduction in stone comminution. All of these studies suggest that cavitation plays a significant role in damaging brittle objects.

The final mechanism of stone breakage to be considered defines stone breakage in terms of a dynamic fracture process, in which the damage induced by SWL accumulates during the course of the treatment, leading to the eventual destruction of the stone. Essential to this process are nucleation, growth, and coalescence of flaws within the stone caused by a tensile or shear stress (Fig. 54-13). Because renal calculi are not homogeneous but rather have either a lamellar crystalline structure bonded by an organic matrix material or an agglomeration of crystalline and non-crystalline material there are numerous sites of preexisting flaws (microcracks). All of the fracture mechanisms described have the potential to generate progressive damage to the interior of the stone. By use of the cohesive-zone model, a mathematical approach of predicting the qualitative features of transient microcrack damage accumulation, Lokhandwalla and Sturtevant (2000) were able to calculate the number of shock waves required for a spall-like failure to occur in a typical calcium oxalate monohydrate calculus. The values they determined had a range of two orders of magnitude (30 to 3000 shocks), which is well within the clinical dose presently used to treat patients. These investigators further suggested that mechanisms other than spall are also likely to inflict damage to stones and spall may be a factor only in a small portion of the stone.

Bioeffects: Clinical Studies

Acute Extrarenal Damage. SWL induces acute injury in a variety of extrarenal tissues (Evan et al, 1991, 1998). SWL has been associated with trauma to organs such as the liver and skeletal muscle, as evidenced by elevated levels of bilirubin, lactate dehydrogenase, serum aspartate transaminase, and creatine phosphokinase within 24 hours of treatment (Lingeman et al, 1986; Ruiz Marcellan and Ibarz Servio, 1986; Parr et al, 1988). These parameters begin to fall within 3 to 7 days of SWL treatment and are normal at 3 months. Other findings of damage outside the kidney have included reports of visceral injuries, such as perforation of the colon, hepatic hematoma, splenic rupture, pancreatitis, and abdominal wall abscess. Extrarenal vascular complications have been reported to occur as well, such as rupture of the hepatic artery, rupture of the abdominal aorta, and iliac vein thrombosis. Thoracic events, such as pneumothorax and urinothorax, have even been described. Fortunately, these events are all exceedingly rare and have generally been presented as isolated incidents.

Figure 54-13. Coalescence of microcracks with a main crack. The undamaged stone has some initial flaws or microcracks of known length. These flaws occur in renal calculi either at a lamellar crystalline structure bonded by an organic matrix material or at an agglomerate of crystalline and noncrystalline material. When stressed, these microcracks grow until they coalesce with the main crack, and because this event is repeated throughout the stone, it eventually fragments. (Reproduced with permission from Dr. Bradley Sturtevant.)

In addition, early clinical studies noted that shock waves could induce cardiac arrhythmia, an observation that led to electrocardiographic synchronization with R-wave triggering on the Dornier HM3 device (Chaussy and Schmiedt, 1984). However, later clinical studies with non-water bath lithotripters have concluded that treating ungated to cardiac rhythm is safe.

Although the lithotripter is characterized by the spatial distribution of its acoustic output (the focal zone, or F2), it is known that high acoustic pressure does extend beyond this zone (Fig. 54-14). Therefore it is reasonable to expect that organs other than the kidney are exposed to stresses sufficient to cause injury. One such organ is the pancreas; a retrospective follow-up study from the Mayo Clinic suggests that patients who underwent SWL for the treatment of kidney stones in 1985 were at increased risk for developing diabetes mellitus compared with controls (Krambeck et al, 2005). The development of diabetes was related to the total number of shock waves and the power level of the lithotripter. Although these data are provocative, there were a number of limitations of the study, including that the stone disease of the SWL cohort was more severe than that of the control cohort, a family history of diabetes was not ascertained for either group, and the data for the SWL group were collected by self-report questionnaire whereas the control group was examined by chart review. Several other groups have subsequently investigated this subject; however, these findings have not been confirmed by any other study (Sato et al, 2008; Makhoul et al, 2009; Chew et al, 2012). Notably, de Cogain and associates (2012) performed a population-based study of Olmsted County, Minnesota, and did not find any association between SWL and diabetes.

Acute Renal Injury: Structural and Functional Changes. Virtually all patients who undergo SWL for renal stones demonstrate hematuria after approximately 200 shock waves. Hematuria is so common that it may be considered an incidental finding, and its severity is rarely of concern. Although hematuria was initially considered to be a consequence of irritation of the urothelium as stones were fragmented by shock waves, it is now known that such is not the case. Detailed morphologic studies have demonstrated that shock waves rupture blood vessels and can damage surrounding renal tubules (Fig. 54-15). SWL is now known to induce such structural changes in the treated kidney in the majority, if not all, of SWL patients, regardless of the type of lithotripter employed (Box 54-1).

In porcine subjects, the preferred animal model for studying acute renal injury, SWL traumatizes vessels ranging in size from the glomerular and cortical capillaries and vasa recta, to the larger arcuate and intralobular vessels. The resulting hemorrhagic lesion generally extends from cortex to medulla and comprises torn blood vessels with platelet aggregation and red blood cells in the interstitial space (Figs. 54-16 and 54-17). Affected renal corpuscles typically show breaks in the Bowman capsule, blood in the urinary space, and damage to the podocytes and mesangial cells (Fig. 54-18). Renal tubules often contain blood cell casts, and the tubular cells may show ischemic changes. In the setting of a more severe injury, complete necrosis of the endothelium and vascular smooth

Figure 54-14. Predicted peak positive pressure in a Dornier HM3 lithotripter. The pressure is not focused to a point but extends over a finite volume.

Figure 54-15. Macroscopic photomicrograph of a coronal section through the kidney of a juvenile pig (~6 weeks old) treated with 2000 shocks at 24 kV by an unmodified Dornier HM3 lithotripter and examined 4 hours after treatment. The region of intraparenchymal hemorrhage has been colored red by an automated computer color recognition program. Note that the lesion involves multiple papillae and in some regions extends through the cortex to the renal capsule, where a subcapsular hematoma may develop.

Figure 54-16. Light micrographs of an acute shock wave lithotripsy (SWL)-induced lesion at F2 (A) and subsequent chronic changes at a similar site 3 months after SWL treatment (B). Each pig kidney was treated with 2000 shock waves at 24 kV by an unmodified Dornier HM3 lithotripter. The acute lesion is characterized by numerous sites of hemorrhage (arrows) that extend from an individual renal papilla (asterisk) to the outer cortex of the kidney. Note a subcapsular hematoma (double arrows, A). The tissue section in B is similar in location to that seen in A but is shown at 3 months after SWL. A rectangle outlines the site of focus 2. Within that region there is complete loss of the renal papilla (the asterisk indicates where it should be), and only scar tissue is found in the adjacent cortical tissue (arrow).

BOX 54-1 Renal Side Effects of Shock Wave Lithotripsy in Experimental Canine and Porcine Animal Models

ACUTE HISTOLOGIC CHANGES

- Venous thrombi
- Cellular disruption and necrosis
- Mild tubular necrosis (ischemic changes)
- Intraparenchymal hemorrhage
- Tubular dilation and cast formation
- Damage and rupture of veins and small arteries
- Rupture of glomerular and peritubular capillaries

CHRONIC HISTOLOGIC CHANGES

- Nephron loss
- Dilated veins
- Streaky fibrosis
- Diffuse interstitial fibrosis
- Calcium and hemosiderin deposits
- Hyalinized and acellular scars from cortex to medulla

muscle may result. A typical clinical dose of 2000 shock waves with the Dornier HM3 lithotripter, operated at 24 kV with shock waves delivered at 2 Hz, produces a lesion measuring 5% to 6% of the functional renal volume (Fig. 54-19).

There have been reports of moderate-to-severe renal injury occurring after SWL, generally manifesting as a hemorrhagic event. Hematoma rates range from less than 1% to as high as 20%, depending on the type of lithotripter used and the treatment parameters employed, as well as the radiographic modality and timing of imaging follow-up. In addition, the later generation of lithotripters that have small focal areas and extremely high peak positive pressures are reported to produce higher clinically significant hematoma rates (3% to 12%), a trend that is worrisome (Thuroff et al, 1988; Ueda et al, 1993; Kohrmann et al, 1995; Piper et al, 2001). Several risk factors for the development of a post-SWL hematoma have been identified (Box 54-2). Dhar and associates (2004) reported that the probability of a subcapsular hematoma increased 2.2 times for every 10-year increase in the patient's age. Knapp and associates (1988) found patients with existing hypertension to be at increased risk for the development of perinephric hematomas as a consequence of SWL. In particular, those patients having unsatisfactory control of their hypertension at the time of SWL had the

Figure 54-17. Low-magnification transmission electron micrograph demonstrating injury to a medium-sized artery located within F2 of a pig treated with 2000 shock waves at 24 kV. The shock wave-induced injury to the right side of this vessel resulted in a rupture site that permitted extravasation of blood into the nearby interstitium. The site of injury in the vessel wall is plugged with a clot (arrows).

Figure 54-18. This series of light microscope panels depicts the injury seen in the cortex and medulla from an animal treated with 2000 shock waves at 24 kV by an unmodified Dornier HM3 lithotripter. A and B illustrate extensive injury in both cortex and medulla. Within the cortex, disruption of arterial walls with hemorrhage (double arrows) is noted near sites of intraparenchymal bleeding (x). The first site of injury appears to occur in the renal medulla, where damage is noted to small vessels, which causes intraparenchymal hemorrhage (arrows) adjacent to damaged collecting ducts (arrowheads).

BOX 54-2 Acute Renal Side Effects: Risk Factors for Shock Wave Lithotripsy

- Age
- Obesity
- Coagulopathies
- Thrombocytopenia
- Diabetes mellitus
- Coronary heart disease
- Preexisting hypertension

Figure 54-19. Shock wave lithotripsy-treated and control kidneys imaged by positron emission tomographic scanning before and immediately after treatment with 3500 shock waves to the lower pole, at level six, with a DoLi 50 device. The site of focus 2 (F2) (lower pole) on the shocked kidney shows a 50% reduction of renal blood flow (arrow).

Figure 54-20. Magnetic resonance image taken 24 hours after shock wave lithotripsy with 1200 shocks at 22 kV (by an unmodified Dornier HM3 lithotripter) shows a large subcapsular hematoma (arrows) in the treated (left) kidney.

highest incidence of hematoma formation. Additional risk factors for hemorrhage were diabetes mellitus, coronary artery disease, and obesity, all of which suggest a link to a vascular disorder. The appearance of renal hematomas can range in severity from a mild contusion localized within the renal parenchyma to a large hematoma (Fig. 54-20) associated with severe bleeding, possibly necessitating blood transfusion or rarely even angiographic embolization. Although some hematomas may persist for many months to years, it has been reported that most resolve within weeks and without long-term sequelae.

Chronic Renal Injury: Structural and Functional Changes. At present there is a paucity of information on the chronic injury

TABLE 54-1 Blood Pressure Changes in Patients Treated with Shock Wave Lithotripsy

STUDY	LENGTH OF STUDY (mo)	NO. SHOCKS		CHANGE IN INCIDENCE OF HYPERTENSION	CHANGE IN DIASTOLIC BLOOD PRESSURE

induced by SWL, the result in great part of the lack of experimental animal studies. Nonetheless, it is well accepted that shock waves damage blood vessels, and the resulting hemorrhage initiates an inflammatory response that ultimately leads to scar formation. Parenchymal fibrosis, a precursor to renal scarring, is seen as early as 1 month after SWL, and scar formation also has been reported to be a dose-dependent phenomenon. Clinically there are **four potential chronic renal changes that may be associated with SWL treatment**. They are an accelerated rise in systemic blood pressure, a decrease in renal function, an increase in the rate of stone recurrence, and the induction of brushite stone disease. All four effects appear to be linked to the observation that the acute renal injury at F2 progresses to scar formation.

The possibility that SWL might be associated with significant changes in systemic blood pressure was first suggested by [Peterson and Finlayson \(1986\)](#) and has been investigated by others ([Table 54-1](#)). [Lingeman and coworkers \(1987\)](#) reported that 8.2% of 243 patients who were normotensive at the time of SWL developed blood pressure changes requiring antihypertensive medication. Mean follow-up in this group of patients was 1.5 years, giving an annualized incidence of hypertension of 5.5%. Similar data have been reported by [Williams and Thomas \(1989\)](#). After these reports suggesting that hypertension could be a long-term complication of SWL, a large study involving almost 1000 patients was undertaken at the Methodist Hospital of Indiana ([Lingeman et al, 1990](#)). This study found a small but statistically significant change in diastolic blood pressure associated with SWL therapy. The observed effect of SWL on diastolic pressure change persisted even after controlling statistically for other variables that might be associated with variation in blood pressure, such as age, sex, pretreatment baseline blood pressure, and number of treatment sessions. [Janetschek and colleagues \(1997\)](#) performed a prospective study that demonstrated age was a significant risk factor for post-SWL hypertension, with an increase in intrarenal resistive index observed in patients 60 years of age and older. The mechanism of hypertension after SWL is not well elucidated. Although subcapsular hematomas can induce hypertension, such changes are generally transient. There has been a report, however, of mesangial proliferation in porcine models after SWL that could induce hypertensive changes.

SWL treatment may also be associated with a long-term reduction in renal function. [Williams and associates \(1988\)](#) found a **significant decrease in the percentage of effective renal plasma flow 17 to 21 months after SWL for patients with two kidneys**. [Orestano and colleagues \(1989\)](#) noted that patients receiving more

than 2500 shocks had a reduction in creatinine clearance and a prolongation of ^{131}I -Hippuran transit time 30 days after SWL in the treated kidney; in some cases, similar findings were noted in the contralateral kidney. [Lingeman and associates](#) reported that patients with a solitary kidney demonstrated elevated serum creatinine levels 5 years after SWL ([Brito et al, 1990](#)). These observations stand in contrast to the early reports by [Chaussy and Fuchs \(1986\)](#), which suggest a significant increase in renal function 3 months to 1 year after SWL. In addition, a longer follow-up study of patients treated in Munich failed to confirm this increase in renal function ([Liedle et al, 1988](#)).

An additional concern is that **stone recurrence rates may be higher after SWL because of residual stone debris** ([Pearle et al, 1999](#)). A study by [Carr and associates \(1996\)](#) documented new stone formation in 298 consecutive patients who initially were determined to be stone free after SWL and compared those findings with those of 62 patients treated by PNL. Their data showed a significant increase in the rate of new stone formation within 1 year of SWL treatment compared with PNL. The authors suggested that fine sand debris generated from SWL treatment remained in the kidney and gravity acted to position it as a nidus in the calyceal system.

A significant increase in the number of calcium phosphate stone formers has been reported during the past three decades ([Mandel et al, 2003](#); [Parks et al, 2004](#)). An intriguing finding in the work by Parks and colleagues was that when all kidney stone formers were analyzed for the number of SWL procedures, the **calcium phosphate stone formers had received a significantly higher number of procedures than did the idiopathic calcium oxalate stone formers when rates were adjusted for number of stones and duration of stone disease**. Furthermore, the brushite stone formers had received a significantly greater number of SWL treatments than had the apatite stone formers. The histopathologic examination of the brushite stone formers revealed advanced levels of tissue changes in the renal cortex and papilla that included interstitial fibrosis, tubular atrophy, glomerular obsolescence, and deposition of large amounts of biologic hydroxyapatite in the lumens of inner medullary collection ducts ([Evan et al, 2005](#)). Although these data do not establish a cause-and-effect relationship, clearly there is an association between brushite stone disease and high levels of SWL treatment sessions. Because apatite stone disease is likely to be related to higher urine pH levels in these patients, animal studies that showed the initial site of SWL injury to be localized to the microvessels and collecting duct of the renal papilla may explain the loss of control over normal urinary fluid pH.

Mechanism for Tissue Injury

The mechanism for the traumatic effects of SWL is not known, although [Delius and colleagues \(1988\)](#) have speculated that the violent collapse of cavitation bubbles generated by the shock waves is primarily responsible for the cellular changes ([Box 54-3](#)). This concept is based on data showing that cavitation bubbles are present during shock wave application and that lithotripter shock waves can cavitate water and blood in vitro ([Coleman et al, 1987](#)). [Crum \(1988\)](#) documented that SWL does produce acoustic cavitation, possibly as the result of the high intensity of the shock wave amplitude and noted that the cavitation microjets are sufficiently forceful to pit or deform metal test foils. [Zhong and coworkers \(2001\)](#) suggested that it is expansion of the bubbles in a vessel that will lead to rupture of the wall of that blood vessel, testing this in an in vitro setting.

No group had been able to positively detect and validate acoustic cavitation within the kidney during SWL treatment until [Bailey and associates \(2005\)](#) created a passive cavitation detection system using two confocal spherical bowl piezoelectric transducers. This device was used for coincidence detection of cavitation bubble emissions within a $2 \times 2 \times 2$ -mm sampling volume centered on F2 of a Dornier HM3 lithotripter. An ultrasound scan head targeted at this spot was used to image echogenicity in and around the sample volume. Signal (passive cavitation detection, hyperechoic spots) was intense in the urinary space during SWL treatment, and a signal was also seen in the renal cortex after only 1000 shocks. At that time a small fluid space was noted at the site of the parenchymal signal. These data suggest that **once blood vessels have been ruptured and blood has collected in pools there is a greater potential for cavitation to occur. The pooling of blood provides a large fluid-filled space for cavitation bubbles to grow and collapse.** In this model the accuracy of tissue targeting was confirmed by inducing a lesion with high-intensity focused ultrasound. Further evidence that cavitation plays a role in tissue injury comes from a study by [Evan and associates \(2002\)](#) in which the degree of tissue injury was compared between a standard rigid reflector and a pressure release reflector. The pressure release reflector generates a shock wave in which the negative tail precedes the positive peak, resulting in a suppression of cavitation activity. No injury was detected in the kidneys treated with the pressure release reflector; the standard rigid reflector induced the expected lesion.

Techniques to Optimize Shock wave Lithotripsy Outcome

For all lithotripters the urologist has the ability to control a number of device parameters that may affect the ultimate treatment outcome ([Box 54-4](#)). These parameters include the acoustic output and focal volume that are employed, optimal coupling, the number of shock waves administered, the rate at which they are dispensed, and the power or voltage that is used. In addition, other intraoperative

factors that may affect stone breakage can be controlled, such as anesthetic technique.

Although all lithotripters generate waveforms that are fundamentally similar, lithotripters may be distinguished from one another by the peak pressure and spatial extent of their acoustic field. The physics of acoustics dictate that the pressure field of a lithotripter is focused not at a particular point in space but rather is distributed over a volume of space. Most commonly, that focal zone is a cigar-shaped region, although the volume of that zone may differ greatly among devices. Recent in vitro studies suggest that the focal width generated by a lithotripter affects stone breakage; a wider focal width has been reported to increase the likelihood of stone breakage ([Sapozhnikov et al, 2007](#)). Because the kidney tends to move, as a consequence of respiratory motion, the stone may move in and out of a narrow focal zone. Another potential drawback of a narrow focal zone is that less energy may be deposited into the stone. When the focal zone is narrower than the stone being treated, the tensile stress inside a stone is reduced; for the stone to be subjected to the full force of shear stress, the outer surface of the stone must be subjected to high-pressure shock wave energy.

The first-generation lithotripter was a water bath design that was a large, stationary machine. The present generation of lithotripters has dry treatment heads, which make them smaller and more easily transportable. However, they require a coupling medium, such as gel or oil, to join the patient to the device. Optimal coupling permits the efficient transfer of energy from the lithotripter to the patient; poor coupling will reduce stone breakage. Most commonly, energy transfer through a coupling medium is attenuated by air pockets in the coupling interface itself. Decoupling and recoupling, which may occur during repositioning of a patient during SWL, can generate large-volume air pockets in the coupling medium. Such air pockets can have a dramatic effect on treatment efficacy; air pockets of just 2% of the coupling interface reduce breakage by 20% to 40% ([Pishchalnikov et al, 2006](#); [Neucks et al, 2008](#); [Li et al, 2012](#)). Although there is no way to monitor coupling during treatment, simple steps can minimize the likelihood of air pockets developing. Dispensing gel from a squirt bottle and rubbing the gel by hand to cover the treatment head and skin degrades the coupling interface. Improved coupling can be achieved by delivering a large volume of gel as a mound dispensed from the stock jug and allowing the gel to spread on contact between the treatment head and the skin.

During an SWL treatment session the urologist can directly control the rate at which shock waves are delivered and the number of shock waves dispensed. In a recent literature review and meta-analysis of randomized controlled trials evaluating different shock wave delivery rates, a rate of 60 shocks per minute was found to break stones more effectively than 120 shocks per minute ([Semins et al, 2008](#)). Cavitation is thought to play a role in this effect,

BOX 54-3 Reversible and Irreversible Injury

REVERSIBLE CHANGES

Mild tubular necrosis
Casts and red blood cells in tubular lumen
Vacuolar changes of tubular lumen
Mild interstitial edema and hemorrhage

IRREVERSIBLE CHANGES RESULTING IN LOSS OF RENAL TISSUE

Disruption of nephrons
Extensive interstitial edema
Large hematomas of cortex and medulla
Rupture and occlusion of veins and arteries
Fracture of glomerular and peritubular capillaries

BOX 54-4 Factors That Induce the Degree of Renal Trauma Associated with Shock Wave Lithotripsy

AGGRAVATING FACTORS

Number of shocks
Period of shock wave administration: Shorter period increases damage
Accelerating voltage: Higher voltage increases damage
Type of shock wave generator: First- versus second/third-generation devices
Kidney size: Juvenile versus adult
Preexisting renal impairment

MITIGATING FACTORS

Pretreatment with 100 to 500 shocks at low energy level to reduce lesion size
Treatment at a slow rate of shock wave delivery (≤ 60 shocks/min)

because the dynamic bubbles are given a longer time interval to dissipate with a slower rate and therefore have less of a shielding effect and energy draw from subsequent shocks. The disadvantage of a slow rate is, of course, a longer treatment time, particularly if the number of shock waves being delivered is predetermined. However, slowing the rate also has been shown to be protective of kidney vasculature (Evan et al, 2007). The lowest number of shock waves possible should be used to reduce renal injury, but this number is generally predetermined and many patients are likely to be overtreated. Risks and benefits need to be weighed regarding possible overtreatment versus need for further procedures when deciding on shock wave number.

Another parameter urologists adjust is the energy setting on the machine. Increasing the power setting on most electromagnetic lithotripters actually narrows the focal zone, which, as discussed earlier, decreases stone breakage and may also increase the risk for renal injury and renal hematoma (Connors et al, 2000). In the past several years, studies have shown that “ramping up” the energy of the lithotripter can be protective of renal injury (Fig. 54-21). Lesion size is decreased after pretreatment with low-energy shock waves (100 to 2000 at 12 kV followed by 24 kV) (Willis et al, 2006). Interestingly, Connors and coworkers (2009) showed in a pig model that the voltage that is initiated is less important than the actual ramping up, because pretreatment groups with 100 shock waves at 18 or 24 kV both had significantly smaller lesions than just treating with 2000 shock waves at 24 kV without pretreatment. The reduction in renal injury is thought to be secondary to vasoconstriction because the same beneficial effect was blocked when dopamine was administered (Willis et al, 2006). Handa and associates (2012) reported that a pause in treatment, when switching from low-energy to high-energy settings, is not necessary provided that the delivery of low-energy shock waves lasted at least 4 minutes. In addition, ramping up the voltage has been shown to result in better stone breakage when using the same total shock wave energy (Zhou et al,

2004). With regard to voltage parameters, the technique of ramping up appears to both improve stone breakage and reduce tissue injury.

The original lithotripter, the Dornier HM3, required a general anesthetic for treatment. However, later generations of lithotripters were developed for treatment to be performed without anesthesia. To minimize treatment discomfort the lithotripters were designed with wider aperture, which will spread the acoustic field across a broader area of the patient's skin, reducing skin surface pain. However, this wider aperture resulted in a narrow focal zone, which had a deleterious effect on stone breakage. Interestingly, the higher pressures used with these newer machines result in higher adverse event rates as well. The effect of respiratory motion, as described previously, further hampers stone targeting and acts to reduce stone breakage rates.

To reduce stone motion, urologists can perform SWL with general anesthesia, which will control the patient's respiratory rate and volume. Two clinical studies compared the outcome of SWL performed with intravenous sedation and SWL performed with general endotracheal anesthesia. General anesthesia yielded significantly better outcomes: 78% to 87% stone-free rates versus 51% to 55% with intravenous sedation (Eichel et al, 2001; Sorensen et al, 2002). Because general anesthesia is associated with superior outcomes, this may be the anesthesia of choice for SWL, unless contraindicated for medical reasons.

KEY POINTS: SHOCK WAVE LITHOTRIPSY

- Most patients with uncomplicated kidney stones can be successfully treated with SWL.
- Shock waves break stones via multiple different mechanisms, including both compressive and tensile forces.
- SWL is associated with both anatomic and functional injuries to the kidney.
- The effectiveness of SWL can be enhanced by ensuring optimal coupling of the patient to the lithotripter, treating at a slower rate (60 shocks/min), and treating with general anesthesia.
- The adverse effects of SWL may be reduced by initiating treatment at low power settings and slowly ramping up the power to standard treatment energy.

Figure 54-21. On the left is a coronal section of a kidney from an animal treated with 2000 shocks at 24 kV first to the lower pole (shock wave lithotripsy [SWL] 1) and then an additional 2000 shocks at 24 kV to the upper pole (SWL 2) of the same kidney. The typical lesion (in red) is seen at the lower pole; however, a greatly reduced lesion is seen on the upper pole. These data suggest that a pretreatment protocol might reduce the lesion induced by a clinical dose of shock waves. At right, lesion size is shown in an animal first treated at the lower pole with 500 shocks at 12 kV (SWL 1) and then treated again at the lower pole with 2000 shocks at 24 kV (SWL 2). A greatly reduced lesion is also noted for this protocol.

Percutaneous Nephrolithotomy

Fernstrom and Johansson (1976) first reported the technique of creating a percutaneous tract specifically to remove a stone. Subsequent reports have established PNL as a routinely used technique to treat patients with large or otherwise complex calculi (Alken et al, 1981; Wickham and Kellett, 1981; Segura et al, 1982; Clayman et al, 1984). Advances in surgical technique and technology have enabled the continuous evolution of PNL, allowing the urologist to remove calculi percutaneously with increasing efficiency. Because the percutaneous approach to stone removal is superior to the open approach in terms of morbidity, convalescence, and cost, PNL has replaced open surgical removal of large or complex calculi at most institutions (Matlaga and Assimos, 2002). Furthermore, the number of PNL procedures performed each year in the United States is increasing as patients with more complex health status are treated minimally invasively (Mirheydar et al, 2013). The specific aspects of percutaneous techniques as they relate to stone removal are delineated and discussed in the following section.

Preparation of the Patient

The initial evaluation of the patient who is being considered for PNL should be a complete history and physical examination. A complete medical history will identify patients with an absolute contraindication to PNL, such as uncorrected coagulopathy, as well as those with an active, untreated urinary tract infection (UTI). The placement of a percutaneous nephrostomy drain, without manipulation of the calculus, may be an appropriate

therapy if the stone is associated with obstruction of the renal unit and sepsis. If it is medically feasible, **aspirin and other antiplatelet medications should be discontinued 7 days before the date of surgery** (Mak and Amoroso, 2003). In patients with a higher risk for thrombotic complications, such as those with ball cage aortic valves or mechanical heart valves with atrial fibrillation, bridging therapy with low-molecular-weight heparin may be necessary. In such instances the heparin should be discontinued 24 hours before the procedure and resumed 24 hours postoperatively if feasible based on amount of active hematuria (Riley and Averch, 2012).

Preoperative laboratory evaluation of patients scheduled for PNL should include a complete blood cell count as well as serum electrolyte determinations and renal function tests. Martin and colleagues (2000) reported that it is unnecessary to obtain screening coagulation studies before PNL for an otherwise healthy patient. **Urine culture is mandatory for all patients who undergo PNL;** perioperative antibiotics can be appropriately tailored to culture-specific organisms. Typing and screening of the patient's blood should be performed, although preoperative crossmatching usually is not necessary.

The standard usage of helical computed tomography (CT) to evaluate the patient with urolithiasis has eliminated the need to perform preoperative intravenous urography or retrograde pyelography (Park and Pearle, 2006). **In most cases, the decision to perform PNL may be based on the stone burden displayed on the CT images.** The main advantage of CT is the ability to assess the spatial relationship of the kidney relative to the stone and that of the kidney in relation to adjacent peritoneal and retroperitoneal structures. Retrorenal colon has been reported to be present in less than 1% of all patients, but its incidence may be higher in those who have undergone jejunioileal bypass, those in a nursing home, those with spinal cord injury, or those with spinal deformities such as advanced scoliosis (Sherman et al, 1985; Onder et al, 2014). These patients will benefit from an initial CT scan. Patients with ectopic kidneys, both congenital and iatrogenic (e.g., due to renal allograft, autotransplantation), as well as patients with dysmorphic body habitus because of congenital malformations such as spinal dysraphism also may benefit from cross-sectional imaging before PNL; intra-abdominal structures, such as the bowel, may be located between the skin and the renal access point in such cases. A kidney-ureter-bladder (KUB) radiograph may be obtained immediately before the procedure to verify stone location if there is concern for stone migration. Retrograde pyelography can be performed at the time of the surgical procedure, acquiring information about calyceal anatomy that may aid in selecting the targeted puncture site. However, for certain patients, such as **those with calyceal diverticula or duplicate collecting system, for whom the surgical approach is affected by the diverticulum's relationship to the collecting system, intravenous or retrograde pyelography may be required at the time of initial evaluation.** Radionuclide scanning may be necessary in selected patients, particularly those harboring staghorn calculi, to evaluate differential renal function.

Antibiotics. Although data to support the need for antibiotic prophylaxis during PNL is limited because of the lack of randomized controlled clinical trials, it is generally accepted that antibiotic prophylaxis will reduce infectious complications. Based on the American Urological Association (AUA) Best Practice Statement, the antimicrobial of choice is a first- or second-generation cephalosporin or an aminoglycoside with metronidazole or clindamycin; ampicillin/sulbactam or a fluoroquinolone is recommended as an alternative (Wolf et al, 2008). A multi-institutional study compared patients receiving any type of preoperative antibiotics to those who received no antibiotics and found that the antibiotic group had a lower fever, a lower retreatment and complication rate, and a higher stone-free rate compared to those who did not receive antibiotics (Gravas et al, 2012). Mariappan and associates (2005) reported a prospective controlled study that also found that oral ciprofloxacin 1 week before PNL significantly reduced the risk for postoperative urosepsis. Bag and associates (2011) also found in a prospective randomized trial that 1 week of nitrofurantoin, which reaches therapeutic levels only in the urinary tract, produced similar results, with

a decrease in endotoxemia and systemic inflammatory response syndrome. Importantly, these studies highlight that **urinary calculi may harbor bacteria even though bacteriuria is only intermittently present**, which is particularly true in the patient who has been taking antibiotics in the past. For patients who do have preoperative bacteriuria, stone cultures produced bacteria in 77% of cases in a series reported by Larsen and associates (1986). The most frequently identified organisms were *Proteus mirabilis*, *Escherichia coli*, *Klebsiella* species, *Pseudomonas* species, *Enterococcus* species, and *Enterobacter* species. However, sterile urine does not preclude postoperative bacteriuria, because Charton and colleagues (1986) reported a 35% incidence of bacteriuria after PNL among patients with sterile preoperative urine culture specimens in whom prophylactic antibiotic therapy was not used. Mariappan and associates (2005) also reported that the best correlate with post-PNL sepsis or SIRS is stone culture or renal pelvic urine culture, not bladder urine culture. **The fragmentation of stones, despite sterile urine, may release preformed bacterial endotoxins and viable bacteria that place the patient at risk for septic complications** (Scherz and Parsons, 1987; McAleer et al, 2002, 2003; Paterson et al, 2003). Therefore patients who have radiographic or clinical features suggestive of struvite or in whom infection is suspected should receive broad-spectrum antibiotics before surgery to reduce the risk for sepsis. Antibiotic treatment also may reduce bleeding secondary to inflammation and friability of renal parenchyma. **Approximately one third of patients with an indwelling ureteral stent will, despite sterile urine on a preoperative analysis, be colonized with bacteria; Enterococcus and Staphylococcus epidermidis are the most frequent offending organisms** (Reid et al, 1992; Lifshitz et al, 1999). For patients with indwelling stents, then, a course of antibiotic prophylaxis, particularly for gram-positive organisms, may be beneficial before instrumentation.

Anesthesia. PNL can be performed after the administration of general, epidural, or local anesthesia. Local anesthesia, usually in combination with intravenous sedatives and analgesics, has been reported in a number of centers (Clayman et al, 1983; Hulbert et al, 1986; Preminger et al, 1986; Ohlsen and Kinn, 1993; Li et al, 2013). Local anesthesia may be an option when general anesthesia is contraindicated. A local anesthetic, such as lidocaine, can be delivered into the access tract by use of an 8.3-Fr anesthetic injection catheter with multiple side holes or with a dual-lumen ureteral access catheter (Dalela et al, 2004) or using a 23-gauge spinal needle with injection along the access tract to the renal capsule (Li et al, 2013). Regional anesthesia (e.g., epidural, spinal) can be used for percutaneous procedures, but several problems may be associated with these regional anesthetic techniques. First, a relatively high block is necessary to eliminate all renal pain. Second, distention of the renal pelvis during PNL may cause a vasovagal reaction that is not always prevented by regional anesthesia (Grasso and Taylor, 1997). However, despite these potential complications, several studies have demonstrated the success of regional anesthesia for PNL with decreased overall analgesia requirements and complication rates similar to those with general anesthesia (Karacalar et al, 2009; Singh et al, 2011; Nouralizadeh et al, 2013). Currently, general anesthesia is usually preferred when a more lengthy procedure is planned because it is the best means of protecting the airway when patients are in a prone position. **In cases in which upper pole puncture is contemplated, general anesthesia is preferred because it permits control of respiratory movements, which is essential to minimize the risk for pulmonary complications. A close relationship between the surgeon and the anesthesia team is essential to optimize the outcome of a PNL procedure.** The anesthesiologist should be aware that pulmonary injuries, including hydrothorax and pneumothorax, can occur during PNL; to that end, the anesthesiologist should monitor airway pressures, end-tidal carbon dioxide levels, and oxygen saturation and should auscultate the lungs frequently. Acute anemia from blood loss or dilution also may occur, emphasizing the need for frequent hemodynamic assessments. Because of the large amounts of fluids administered to the patient during nephroscopy there is a potential risk for hypothermia, a disorder associated with an increased risk for morbid cardiac events. Warming of

irrigation fluids as well as patient warming devices may attenuate this risk.

Postoperatively, pain is managed with opioid analgesia and anti-inflammatory medication when not contraindicated. A prospective randomized double-blind placebo controlled trial found no difference in complications but also no improvement in pain when ketorolac was administered continuously compared to placebo after PNL (Grimsby et al, 2012). D'a Honey and associates (2013) assessed the utility of intercostal nerve block in controlling immediate postoperative pain after PNL and found that nerve blockage with 0.5% bupivacaine and epinephrine significantly decreased narcotic use and improved patient-perceived quality of life.

The fundamental techniques of gaining and maintaining percutaneous access are reviewed in Chapter 8.

Stone Removal. After the nephrostomy access has been appropriately dilated and the Amplatz sheath positioned, the urologist can proceed with stone removal by endoscopic techniques. In the early days of PNL several authors reported the successful extraction of renal calculi with Randall forceps (modified to allow passage over a guidewire) or stone baskets under only fluoroscopic, not visual, guidance (Castaneda-Zuniga et al, 1982; Pollack and Banner, 1984). However, fluoroscopically guided stone removal is no longer recommended because it is not as safe or as efficient as the removal of calculi under direct vision.

Physiologic solutions should be used for irrigation during PNL to minimize the risk for dilutional hyponatremia in the event of large-volume extravasation (Carson, 1986). The height of the irrigant during rigid nephroscopy should be maintained at 80 cm or less above the patient to minimize intrapelvic pressure and to prevent fluid absorption through pyelovenous backflow (Miller and Whitfield, 1985). The use of an Amplatz working sheath also prevents elevated intrapelvic pressures. Rigid nephroscopy is performed initially, and stones up to 1 cm in diameter can be grasped with rigid graspers or stone baskets and extracted intact through the 30-Fr Amplatz sheath. Stones larger than 1 cm require fragmentation before extraction. Several intracorporeal lithotripsy techniques are available and are covered elsewhere in this chapter.

Rigid nephroscopy is the preferred method for stone removal; however, only the simplest intrarenal collecting systems can be completely inspected with a rigid nephroscope through a single access. Therefore flexible nephroscopy should be used during every PNL to survey the entire intrarenal collecting system for residual stone fragments. With an Amplatz sheath in place, pressurization of irrigation fluid (up to 300 mm Hg) during flexible nephroscopy is used to adequately distend the collecting system and improve visualization. The entire collecting system should be examined systematically, including the proximal ureter. Injection of contrast material through the flexible nephroscope and occasional fluoroscopy is helpful in maintaining orientation and verifying that each calyx has been inspected. Small stone fragments can be removed with a stone basket passed through the flexible instrument, and larger stones can be fragmented with laser or EHL. Alternatively, fragments may be flushed or manipulated into the renal pelvis, where they may be retrieved more easily with rigid instruments. The goal of PNL is complete or nearly complete clearance of stone material at the time of the primary procedure, which greatly simplifies secondary procedures, if necessary. Furosemide can be administered intravenously when the nephrostomy tube is placed at the conclusion of PNL to promote and to maintain diuresis.

Multiple different sizes and shapes of nephrostomy tubes are currently available for use at time of PNL. The role of nephrostomy tube drainage is to aid in healing of the nephrostomy tract, promote hemostasis, prevent urinary extravasation, drain infection, and allow re-entry if necessary. Recently, tubeless (ureteral stent is left instead of nephrostomy tube) and even totally tubeless (no drainage device used) PNL have been introduced and popularized. Comparison of nephrostomy tube size, shape, and tubeless and totally tubeless procedures is presented elsewhere in the textbook.

Technique Modifications. In an attempt to decrease morbidity association with PNL, modifications have been made to the size of the renal access tract, resulting in the new designations of "mini-

percutaneous nephrolithotomy," "ultra-mini-percutaneous nephrolithotomy," and "micro-percutaneous nephrolithotomy." The mini-PNL was first introduced by Jackman and colleagues in 1997 and decreased using a 13-Fr percutaneous access sheath for stone removal. Subsequent authors have reported their variations of the technique (Lahme et al, 2001; Li et al, 2010). Mini-PNL has been found to be associated with longer operative times and technical limitations on the part of the operating surgeon because of the need to fragment stones into small pieces and poor visualization in the presence of bleeding (Li et al, 2010); however, overall blood loss and transfusion rates with mini-PNL are lower compared to those with standard PNL. Further miniaturization of the access to 11-Fr inner diameter/13-Fr outer diameter ureteral access sheath has led to the ultramini-PNL, where stones are fragmented with a holmium laser and then allowed to pass spontaneously down the ureter. Desai and colleagues (2013) reported a stone-free rate of 97.2% at 1 month postoperatively, with a 16.7% overall complication rate. Most recently, percutaneous lithotripsy has been described using a 4.85-Fr all-seeing needle, termed the micro-PNL. The all seeing needle allows for visualization inside the kidney and directed laser lithotripsy using a 200-micrometer laser fiber (Desai et al, 2011). A recent comparison of micropercutaneous lithotripsy to ureteroscopy found similar stone clearance rates between the two procedures, but a higher rate of postoperative pain and greater decrease in hemoglobin in the micro-PNL patients (Sabnis et al, 2013). Although all of the recent technique modifications work to decrease overall patient morbidity, because of technical limitations with the mini-, ultramini-, and micro-PNL their exact role in the treatment of upper tract nephrolithiasis is uncertain and continues to be defined.

Special Situations

Calyceal Diverticula. Calyceal diverticula are nonsecretory, transitional cell epithelium-lined cystic cavities within the renal parenchyma. A narrow communication with the pelvicalyceal system almost always exists. The incidence of calyceal diverticula diagnosed on routine intravenous pyelography ranges from 0.21% to 0.45% (Hulbert et al, 1986). Although the incidence of calyceal diverticula is low, calculi formation within the diverticula is high as reported in 9.5% to 50% of cases (Jones et al, 1991b). Treatment of calculi within a calyceal diverticulum can be difficult and percutaneous removal has the reported highest treatment success rate of all endourologic minimally invasive treatment modalities (Krambeck and Lingeman, 2009). Percutaneous access into stone-bearing diverticula poses several unique problems. Direct puncture is often difficult because of the small size of the cavity and the frequent occurrence of calyceal diverticula in the upper pole of the kidney. After successful puncture is achieved, negotiation of a guidewire into the renal pelvis is often not possible. A similar situation can occur when a stone fills a calyx so completely that a guidewire cannot be passed through the infundibulum into the renal pelvis or in the rare case of infundibular stenosis. To overcome these difficulties, a special access technique is required.

If the calculi are visible on fluoroscopy it is often preferable to puncture directly onto the stone (Ohlson and Kinn, 1993); however, contrast media can be instilled through a ureteral catheter to help localize the diverticulum and if necessary contrast material can be injected directly into the diverticulum via CT guidance to assist with localization (Matlaga et al, 2006). Direct puncture into the diverticulum allows use of rigid instruments that provide superior visualization compared with flexible instruments that are used in an indirect approach. Optimal visualization is essential in trying to identify the communication between the diverticulum and the renal collecting system. Direct access also allows for easy fulguration of the urothelium by a resectoscope equipped with a roller-ball electrode. Jones and colleagues (1991b) reported that direct percutaneous access into the diverticulum could be established in all but 2 of 24 patients. Likewise, Shalhav and associates (1998) reported that in a group of 30 patients with calyceal diverticula, direct access was performed in 28 patients. When direct puncture fails, a

Figure 54-22. Access into small diverticula. A, Balloon dilator is advanced as far as possible without perforating the back wall of the diverticulum. The working sheath is placed just outside the diverticulum. B, Alligator forceps spread the parenchyma and allow advancement of the nephroscope under vision into the diverticulum. The working sheath is then advanced over the nephroscope and into the diverticulum (C).

neighboring calyx can be punctured and the diverticulum entered indirectly by perforating the wall of the diverticulum or by entering in a retrograde fashion through the diverticular neck (Hedelin et al, 1988). However, results with an indirect approach are inferior (Jarrett and Smith, 1986).

Kim and associates (2005a) have described a single-stage technique for the treatment of patients with calculi residing in a calyceal diverticulum (Fig. 54-22). Once the diverticulum is punctured, a 0.035-inch movable core J-wire is coiled within the diverticulum. It is important to ensure that not only the floppy tip of the wire but also the solid core is coiled within the diverticulum, so that sufficient stabilization is provided for proper placement of coaxial dilators. A second 0.035-inch movable core J-wire serving as a safety wire is then passed through the 10-Fr sheath of the coaxial dilator. With two guidewires coiled within the diverticular lumen, balloon dilation of the track can be performed safely. Care should be taken to avoid perforation of the back wall of the diverticulum. Once the balloon dilator is inflated, the working sheath is passed over the balloon as close as possible to the diverticulum without advancing the balloon. In small diverticula, this results in the placement of the sheath outside the diverticulum. An 11-Fr alligator forceps is passed through the rigid nephroscope and used to follow the wire and gently spread renal parenchyma to allow entry into the calyceal diverticulum under direct vision. Stone material is then extracted. Careful inspection of the urothelium with the rigid nephroscope, and in cases of a large diverticulum a flexible nephroscope as well, is performed in an effort to identify a flattened renal papilla, which suggests an obstructed calyx rather than a diverticulum. The neck of the diverticulum is often difficult to identify because it can be diminutive. Methylene blue injected through the ureteral catheter can facilitate visualization of the ostium. Once a guidewire is passed into the renal pelvis, the neck of the diverticulum can be balloon dilated or incised.

Because calyceal diverticula are lined by a nonsecretory endothelium, most authors advocate fulguration at the time of PNL because this will ablate 76% to 100% of diverticula (Monga et al, 2000; Kim et al, 2005b). Auge and associates (2002) and Turna and associates (2007) also have reported the results of long-term studies in which they found that PNL accompanied by ablation of the diverticulum is associated with superior stone-free rates. Alternatively, one series of 10 patients in which the nephrostomy tube was left in place for

2 weeks suggested that trauma to the wall of the diverticulum caused by the dilation process alone is sufficient to ablate the diverticular lumen (Hulbert et al, 1986). However, Donnellan and colleagues (1999) reported that treatment of 20 patients with calyceal diverticula by dilation or incision of the diverticular neck without fulguration resulted in complete ablation of the diverticulum in only 30% of patients, leading the authors to conclude that fulguration should be performed routinely to ensure diverticular ablation. Typically, after ablation of the diverticulum, a nephrostomy tube is placed for 48 to 72 hours.

Horseshoe Kidney. Horseshoe kidney is the most common congenital renal anomaly found in 1 in 474 abdominal CT scans (Glodny et al, 2009), with a male-to-female ratio of 2:1 (Jones et al, 1991a). The unique location and orientation of the horseshoe kidney are due to the incomplete cephalad migration and malrotation of the kidney, a consequence of the entrapment of the isthmus under the inferior mesenteric artery (Hohenfellner et al, 1992). The uteropelvic junction (UPJ) is commonly deformed owing to the high insertion of the ureter into a typically elongated renal pelvis. The insertion of the proximal ureter is similarly aberrant; it drapes ventrally over the renal symphysis, where it may be compressed by vessels supplying the lower pole and isthmus. Ureteral obstruction that may result from these anomalies can give rise to hydronephrosis, urinary stasis, sepsis, and calculi formation in up to 70% of patients (Jones et al, 1991a; Lampel et al, 1996).

In considering PNL in a horseshoe kidney, the characteristic lower and centrally oriented position of the kidney, the orientation of the collecting system, and the abnormal blood supply should be taken into account. Janetschek and Kunzel (1988) performed post-mortem examinations of six horseshoe kidneys, in situ, and found normal renal arteries in all specimens. However, accessory arteries entering the renal hilum, aberrant polar and isthmus arteries originating from the aorta, and hypogastric and common iliac arteries were noted as well; all blood vessels, except a select few supplying the isthmus, entered the kidney from its ventromedial aspect. Glodny and colleagues (2009) examined CT scans of 90 patients with horseshoe kidneys and found that cephalad the vasculature had little variation; however, more caudally the renal vasculature varied considerably. Therefore, a puncture of the dorsal or dorso-lateral aspect of the kidney will be well away from major renal vessels.

Skoog and associates (1985) reported an association between horseshoe kidney and retrorenal colon. A preoperative CT should be performed to assess the presence of a retrorenal colon as well as to define the stone-bearing calyces. The lower pole calyces lie within a coronal plane, angled medially, and are seldom suitable for direct puncture (Al-Otaibi and Hosking, 1999). However, the upper pole calyces are more posterior and lateral and are often subcostal, providing a convenient and relatively safe route for PNL access. The standard site for PNL (inside the posterior axillary line just caudal to the 12th rib) is punctured, but the angle of the puncture is caudad rather than cephalad. Because most of the calyces of horseshoe kidneys point either dorsomedially or dorso-laterally, they are more favorably positioned for puncture than are normal renal units (Janetschek and Kunzel, 1988). Because of the malrotation of the kidney, the renal pelvis may be more anteriorly located and the length of the nephrostomy tract often exceeds the length of the rigid nephroscope, necessitating the use of flexible nephroscopy or multiple accesses. Flexible nephroscopy also may be required to gain access to the lower medial calyces, where stones are often found.

Raj and associates (2003) reported a multicenter analysis of 24 patients with calculi in a horseshoe kidney who underwent PNL. The overall stone-free rate was greater than 90%, most accesses were upper pole, and flexible nephroscopy was performed in almost all patients. The authors noted that the rigid nephroscope was rarely sufficient to remove the whole stone burden. Miller and associates (2008) reported a similar series of patients undergoing PNL of horseshoe kidneys; upper pole access was used in all cases, as was flexible nephroscopy. A prospective multi-institution study from the Clinical Research Office of the Endourology Society noted similar stone-free results in patients with horseshoe kidneys compared to normal kidneys (76.6% vs. 76.2%) but found operative times to be significantly longer in the patients with horseshoe kidney with a higher rate of overall failed procedures in all patients with renal anomalies (Osther et al, 2011).

Transplantation and Pelvic Kidneys. Urolithiasis is uncommon in patients who have undergone renal transplantation, with a reported incidence of 0.5% to 3% (Harper et al, 1994; Shoskes et al, 1995; Del Pizzo and Sklar, 1999). Factors that may predispose transplant recipients to form calculi include metabolic abnormalities, foreign bodies (nonabsorbable suture material, forgotten stents), recurrent infection, and papillary necrosis. On occasion, calculi may have been present in the donor kidney (Pardalidis et al, 1994). Verrier and colleagues (2012) reviewed their 32-year experience and noted a significant decrease in the incidence of transplant urolithiasis after the introduction of routine ureteral stenting and early intervention for ureteral obstruction after transplantation. Typical renal colic does not occur because the transplantation kidney and ureter are denervated; the presentation may instead resemble acute rejection or acute tubular necrosis (Harper et al, 1994; Rhee et al, 1999). Benoit and colleagues (1996) reported that in a series of 1500 transplantation patients, 12 (0.8%) were diagnosed with urinary calculi. Three patients presented with obstructive anuria, one patient presented with abdominal pain, and eight patients were asymptomatic and diagnosed by ultrasonography. Krambeck and colleagues (2008) found that acute renal failure, hematuria, and UTI were the most common presenting symptoms in 13 renal transplant patients treated with PNL.

Renal allografts present a unique anatomic situation for PNL. The most common surgical anatomy is for the donor left kidney to be placed extraperitoneally into the recipient's right iliac fossa; alternatively, the right kidney is transplanted in the left iliac fossa. In either case, the renal pelvis is located medially, requiring that the kidney be rotated 180 degrees on its axis. Thus the posterior calyces point anteriorly and, consequently, an anterior approach to the kidney is similar to a posterior approach to native kidneys. In the usual percutaneous approach to a transplanted kidney the patient is placed in the lithotomy position, which allows simultaneous cystoscopic access to the bladder. A ureteral catheter is inserted for instillation of contrast material. Access is most safely established (i.e., avoiding intraperitoneal contents) into the lower pole with the

skin puncture as caudal as possible. Percutaneous access to transplanted kidneys is actually facilitated by their superficial location. However, scar formation around the graft may make the initial needle puncture and tract dilation more difficult (Rhee et al, 1999). Once access is established, PNL can be performed by standard methods (Pardalidis et al, 1994; Krambeck et al, 2008). Del Pizzo and Sklar (1999) reported the use of a mini-percutaneous technique in 14 transplantation patients in whom access was established with the aid of intraoperative ultrasonography with a 16-Fr suprapubic peel-away introducer and sheath. No data are available to show an advantage of the mini-percutaneous technique compared with the larger diameter working sheaths. Although delayed closure of the access site after catheter removal in immunosuppressed transplantation patients is a concern, most authors report that even nephrostomy tracts dilated to 30 Fr closed normally (Caldwell and Burns, 1988; Gedroyc et al, 1989; Del Pizzo and Sklar, 1999; Krambeck et al, 2008). Rifaioğlu and associates (2008) reported that not all patients will require tract dilation to 30 Fr, and in some cases acceptable outcomes may be achieved with percutaneous flexible nephroscopy alone.

Patients with ectopic pelvic kidneys necessitate a different and more complicated approach for PNL as a result of their unique anatomy. The incidence of pelvic kidney has been estimated to range from 1 in 2200 to 1 in 3000 in autopsy series (Zafar and Lingeman, 1996). The pelvic kidney is retroperitoneal, posterior to the peritoneum and anterior to the sacrum. Interposing bowel loops between the kidney and the anterior abdominal wall prevent a direct puncture through the anterior abdominal wall. Eshghi and colleagues (1985) first described a laparoscopically assisted PNL technique for pelvic kidneys, a technique that has been further characterized by others (Zafar and Lingeman, 1996; Holman and Toth, 1998; Matlaga et al, 2006). Desai and associates (2007) reported on PNL in pelvic ectopic kidneys using only ultrasound guidance. Although the stone-free rate was 100%, a bowel injury did occur in one patient. Consequently, if laparoscopy will not be used to assist guidance and reflect intervening organs away from the anticipated course of percutaneous access, percutaneous access could be obtained using CT guidance (Fig. 54-23), as described by Matlaga and associates (2003).

Staghorn Calculi/Complex Stones. Patients suffering from staghorn calculi or complex renal calculi remain a challenging problem for the practicing urologist. Most staghorn stones are composed of struvite, and factors that predispose to UTI and retained urine increase the likelihood of struvite stone formation (Gettman and Segura, 1999). However, other crystals, including cystine, calcium

Figure 54-23. Computed tomography–guided percutaneous access of a renal transplant for subsequent percutaneous nephrolithotomy procedure.

oxalate monohydrate, and uric acid, can assume a staghorn configuration. In general, the goal for patients with staghorn calculi should be stone free, because if all of the infected stone debris is not evacuated, urea-splitting bacteriuria may persist, which can ultimately lead to eventual stone regrowth.

The management of patients with staghorn stones by a combined approach must be viewed as primarily percutaneous, with SWL being used only as an adjunct to minimize the number of access points required. Improved PNL techniques incorporating the increasing use of flexible nephroscopy and providing complete or nearly complete clearance of stone material at the time of the primary procedure may have decreased or eliminated the need for additional SWL treatment (Preminger et al, 2005).

Desai (2009) and colleagues published the largest series of staghorn calculi treated with PNL, which included 834 procedures in 773 patients. The overall stone-free rate was 86%, and the authors found that with time, experience, and advancements in technology there was a reduction in operative and hospital duration, tract numbers, reintervention and complication rates, and likelihood of residual fragments. Soucy and colleagues (2009) also published their series of 509 staghorn calculi treated percutaneously. Only 16% of patients required multiple access tracts and transfusion rate was low at 0.8%. Overall stone-free rate was 90%, with 9% of patients requiring a secondary procedure. Duvdevani and colleagues (2007) presented their series of 1585 PNL cases, which included staghorn calculi. Their results demonstrated that as stone surface area increased, stone-free results decreased, with staghorns having an 88.6% stone-free result by KUB. Only 8% of their patients overall required more than one percutaneous access tract, and 24% required a secondary procedure. However, a recent study from the Clinical Research Office of the Endourological Society compared outcomes of PNL in 1466 staghorn calculi to 3869 nonstaghorn calculi patients at 96 centers worldwide (Desai et al, 2011). Those patients with staghorns had a higher rate of multiple access tracts (16.9% vs. 5.0%), higher overall complication rate including bleeding and fever, and lower stone-free rate (56.9% vs. 82.5%).

In general, if a single access tract is to be used in treating complex branching stones, the upper pole is preferred. An upper pole access allows for treatment of the upper pole, renal pelvis, and many lower pole stones using the rigid nephroscope. Midcalyceal stones can then be treated using a flexible nephroscope and holmium laser. When pressurized irrigant is used the debris and fragments created by the holmium laser in most cases will wash out the access sheath or into the renal pelvis, where it can be retrieved with the rigid nephroscope and suction.

Morbid Obesity. Patients with morbid obesity present technical as well as anesthetic challenges during any surgical intervention (Freedman et al, 2002). Often, one or more comorbid factors complicate management of these patients. General anesthesia may be a special concern for obese patients in the prone position because of restricted respiratory capacity that may require higher ventilation pressures intraoperatively. Multiple studies have not demonstrated an increase in overall morbidity in the obese patient undergoing PNL. Pearle and coworkers (1998) were the first to examine the issue of PNL among the obese and found that performing standard prone PNL was not associated with an increased risk for morbidity; in fact, complication and transfusion rates as well as the length of hospitalization were no different compared to those in nonobese patients. Subsequent authors have observed that PNL outcomes are independent of body mass index (BMI) (Koo et al, 2004), including stone-free results (El-Assmy et al, 2006). However, a multi-institution study of 3709 PNL procedures performed across the globe found that complication rates were not associated with BMI, but patients with a higher BMI were more likely to have comorbid conditions, including chronic anticoagulation, and a lower overall stone-free rate (Fuller et al, 2012).

Positioning the morbidly obese patient for PNL can be difficult; and in particular for large patients, two surgical tables may need to be secured together (Hofmann and Stoller, 1992). Patient positioning should be closely inspected, and pressure points should be identified and padded. Hofmann and Stoller (1992) described a

morbidly obese patient who developed acute rhabdomyolysis secondary to crush injuries from placement in the lateral approach; if this technique is used, care must be taken to minimize muscle crush injury. Some authors have used awake intubation and patient self-positioning for the morbidly obese patient to decrease the likelihood of nerve or muscle damage (Wu et al, 2009). The major difficulty in performing PNL in the morbidly obese patient is the long distance from the skin to the collecting system, which may exceed the length of the working sheath or the length of the rigid nephroscope. **Extralong Amplatz working sheaths (≥ 20 cm) and extralong rigid nephroscopes are now available that can overcome this challenge.** Alternatively, the Amplatz sheath can be secured by a suture, allowing easy retrieval even when it migrates under the skin. On occasion, when the long Amplatz sheath is not sufficient to reach the kidney, an incision can be made through the subcutaneous tissue to the muscles of the flank, and the PNL tract created from the level of the muscle sheath (Curtis et al, 1997). Alternative instrumentation also can be employed; Giblin and colleagues (1995) described the successful use of a 30-Fr gynecologic laparoscope (with a working length of 27 cm) in patients in whom the skin-to-stone distance precluded the use of standard access sheaths and nephroscopes. Another possibility is to dilate the tract and place a nephrostomy tube for 1 week to let the tract mature. In some cases, maturation of the tract allows the kidney to fall back posteriorly closer to the skin, allowing the use of standard nephroscopic instrumentation. Flexible nephroscopy also can be performed through the mature tract, reducing the necessity of rigid nephroscopy (Hofmann and Stoller, 1992). Liberal use of flexible nephroscopy in obese patients improves the stone-free rate and decreases the need for additional access (Pearle et al, 1998).

After stone removal, if a nephrostomy tube is placed, consideration should be given to the type of nephrostomy tube used. **Tube displacement tends to occur more often in morbidly obese patients**, so balloon-type catheters or re-entry Malecot catheters may be preferable (Carson et al, 1988). Alternatively, if a Cope loop catheter is used, placement of a ureteral catheter should be considered to ensure that access to the kidney is not lost should the nephrostomy tube become displaced.

Bilateral Simultaneous Percutaneous Nephrolithotomy

Patients with large, bilateral stone burdens present a formidable challenge to the urologist; rendering these patients stone free can require staged procedures and multiple anesthetics. In 1987, Colon-Perez and associates (1987) first reported simultaneous bilateral PNL in a series of three patients. Since that time the procedure has evolved and several dictums have been established. It is recommended that either the side that is more symptomatic or the side that is more difficult be treated first. Patients may be positioned prone or with the treated side elevated.

Most groups have reported that there is a marked advantage in terms of hospitalization and convalescence, suggesting that a simultaneous bilateral PNL provides the patient a less morbid, more rapid method of stone resolution than does staged PNL or a sandwich technique (Dushinski and Lingeman, 1997; Nadler et al, 1998; Holman et al, 2002). Silverstein and associates (2004) also reported that stone-free rates, blood loss per operation, and transfusion rates for simultaneous and staged bilateral PNL were similar. Furthermore, the reduced total operative time, hospital stay, and total blood loss along with the requirement for only one anesthesia session makes simultaneous bilateral PNL an attractive option for selected patients. However, a recent evaluation using the Clavien scoring system for postoperative complications found that bilateral PNL was associated with a higher rate of low-grade complications compared to unilateral single access PNL (Kadlec et al, 2013). Desai and associates (2007) have issued a caveat that patients with exceptionally large stone burdens or complex intrarenal collecting system anatomy should not be selected for a simultaneous bilateral PNL. Bagrodia and associates (2009) performed an outcome cost analysis of simultaneous bilateral PNL, confirming the superior morbidity and convalescence of this approach.

Taking all of the evidence together, should a simultaneous bilateral approach be selected the second side should be pursued only if no significant bleeding is encountered on the first side, the first side did not take an undue amount of time, the patient is clinically stable, and the anesthesia team is agreeable.

Complications

Even for the most experienced urologist, major complications can still occur in up to 7% of patients undergoing PNL and minor complications may be encountered in up to 25% of patients (Preminger et al, 2005). **Hemorrhage is the most significant complication of PNL, with transfusion rates reported to be from less than 1% to 10%.** A multi-institution study of more than 5000 patients from 96 different centers reported an overall transfusion rate of 5.7% (Yamaguchi et al, 2011). Risk for hemorrhage was associated with stone burden and operative duration. Bleeding from an arteriovenous fistula or pseudoaneurysm that requires angiographic embolization occurs in less than 1% of patients (Keoghane et al, 2013). Other potential complications include sepsis (postoperative temperature $> 38.5^{\circ}\text{C}$ [101.3°F] is found in almost one fourth of patients undergoing PNL), adjacent organ injury (bowel, spleen), failed access, and perforation of renal pelvis and ureter. The need for open surgery is rare and mostly reported as part of early experience in various studies. The mortality rate of PNL is between 0.03% and 0.8% (Lang, 1987; Lee et al, 1987; Henriksson et al, 1989; Jones et al, 1991a; Lam et al, 1992; Segura et al, 1994; Dyer et al, 1997; Matlaga et al, 2004; de la Rosette et al, 2011). When supracostal puncture is performed, the risk for pneumothorax or pleural effusion requiring drainage can vary widely from 1.8% to as high as 8% in historical series (Picus et al, 1986; de la Rosette et al, 2011). Finally, failure of equipment is an often ignored but significant potential complication. Experience of the center performing the PNL procedure also can contribute to overall complication rates and stone-free results. Opondo and colleagues (2012) evaluated PNL performed at 96 centers worldwide. The results of their study found that as their institution case volume increased, so did stone-free rates. Complication rates and duration of stay diminished with increasing case volume after adjusting for stone burden and other cofactors. The highest stone-free results and lowest complication rates were observed in centers with greater than 120 cases per year.

During initial experiences with PNL, concern was expressed about the extent of renal damage caused by the creation and dilation of the transparenchymal nephrostomy tract. However, although some scarring does occur along the percutaneous tract, there is little or no significant effect on renal function (Eshghi et al, 1989).

Because the kidney is an extremely vascular organ, some degree of bleeding occurs during every PNL. Significant bleeding usually requires cessation of the procedure because of impaired visualization. In most cases the source of hemorrhage is venous and placement of a nephrostomy tube is usually sufficient to control the bleeding. If bleeding persists despite the placement of a nephrostomy tube, clamping the tube for a time may facilitate the tamponade of any bleeding points. If these measures do not control the hemorrhage, a Kaye nephrostomy tamponade balloon catheter should be placed. The Kaye nephrostomy tube incorporates a low-pressure 12-mm balloon that may be left inflated for prolonged periods to tamponade bleeding from the nephrostomy tract (Kaye and Clayman, 1986). If bleeding persists despite placement of a Kaye catheter, immediate angiography should be performed to identify a possible arteriovenous fistula or false aneurysm. Angiography is both diagnostic and therapeutic, because arteriovenous fistulas and false aneurysms are best managed by embolization. In the rare event that bleeding cannot be controlled with angiography, partial nephrectomy may be required.

PNL can lead to some absorption of irrigation fluid; therefore the use of physiologic irrigating solutions is mandatory. The amount of absorbed fluid depends mostly on the irrigant pressure and the length of the procedure; thus an access sheath should be used. Larger amounts of fluid absorption may occur with extravasation of fluid as a result of collecting system perforation. Extravasation

usually occurs into the retroperitoneal tissue and may be noted by medial displacement of the kidney during fluoroscopy. Minor perforations are common during PNL; premature termination of the procedure usually is not necessary when a low-pressure system (e.g., Amplatz sheath) is being used. However, with more significant perforations, termination of the procedure and nephrostomy drainage are advisable. Intraperitoneal extravasation is a less common but potentially more serious complication than retroperitoneal extravasation. Because the patient is prone, abdominal distention may be difficult to recognize, although the anesthesiologist will usually note a gradual rise in the patient's diastolic blood pressure with consequent narrowing of the pulse pressure and increase in central venous pressure; in advanced cases, ventilation may become difficult because of increased abdominal pressure. Early recognition of major extravasation is crucial. Before the standard use of access sheaths it was recommended that accounting of the irrigant input and output be maintained and if a discrepancy of more than 500 mL were encountered the procedure should be aborted (Lee et al, 1986; Segura, 1993). However, a strict accounting of irrigating fluid balance is not necessary when an access sheath is properly placed. Intraperitoneal extravasation may be treated by vigorous diuresis; alternatively, peritoneal drainage has been reported (Carson and Nesbitt, 1985).

When a supracostal puncture is performed, extravasation of irrigant into the pleural cavity may occur. The use of a working access sheath tends to minimize extravasation into this space because intrarenal pressure remains low. The chest should be examined at the end of PNL procedures in which a supracostal puncture is used. Fluoroscopy with use of the C-arm is usually sufficient to examine for pneumothorax or hydrothorax (Ogan et al, 2003). If the surgeon has a high index of suspicion for a thoracic complication, a chest radiograph may be obtained postoperatively. If a greater than 10% pneumothorax or hydrothorax occurs, aspiration is generally sufficient because lung injury is extremely rare. Should the pneumothorax recur, a chest tube should be placed. Ogan and Pearle (2002) described placement of a chest tube under fluoroscopic guidance at the time of the PNL.

Colonic injury is an unusual complication and is often diagnosed on postoperative nephrostogram or CT imaging, although passage of gas or feculent material through the nephrostomy tract, intraoperative diarrhea, and hematochezia or peritonitis are all signs of a possible colonic perforation. Typically, the injury is retroperitoneal; thus signs and symptoms of peritonitis are infrequent. If the perforation is extraperitoneal, management may be expectant, with placement of a ureteral catheter or double-J stent to decompress the collecting system and withdrawal of the nephrostomy tube from an intrarenal position to an intracolonic position to serve as a colostomy tube (Gerspach et al, 1997). The colostomy tube is left in place for a minimum of 7 days and removed after a nephrostogram or a retrograde pyelogram shows no communication between the colon and the kidney (LeRoy et al, 1985; Wolf, 1998).

Ureteroscopic Management of Ureteral Stones

Basic ureteroscopic techniques and intracorporeal lithotripsy techniques have been reviewed elsewhere. Herein, issues of anesthesia and specific points of technique and complications of ureteral stone management are reviewed.

The increasing miniaturization of and improvements in the technology of ureteroscopy have greatly altered the anesthetic considerations associated with this procedure. Ureteroscopy was initially performed exclusively under general or regional anesthesia as a consequence of the large-caliber ureteroscopes that were available. However, as ureteroscopes have become more diminutive, intravenous sedation, or sedoanalgesia, has provided another practical anesthetic option for patients harboring ureteral stones. The short duration of modern sedoanalgesic agents allows rapid relief of pain, efficient titration of analgesia, and rapid recovery after the procedure. Ureteroscopy can be safely and efficiently performed under local or intravenous sedation, with success rates equivalent to those of patients undergoing general or regional anesthesia (Cybulski

et al, 2004; Park et al, 2004). Because most ureteral orifices will accommodate a 6- to 7-Fr device, immediate access to ureteral calculi with a 7-Fr flexible ureteroscope is possible. Furthermore, the small-diameter fibers of the holmium:YAG laser allow the immediate treatment of ureteral calculi.

The ability to fragment and remove calculi with a ureteroscope has dramatically advanced the urologist's ability to render patients stone free with a single procedure. Early stone-free results with flexible ureteroscopy did not exceed those of in situ SWL (Drach et al, 1986; Bagley, 1990; Frang et al, 1992; Mogensen and Andersen, 1994). However, as smaller ureteroscopes were introduced and the holmium:YAG laser became available, success rates for ureteroscopy have increased (Preminger et al, 2007). Although it is a more invasive technique than SWL, ureteroscopy with small, rigid or flexible endoscopes is the most efficient technique for treatment and removal of ureteral stones. Patients desiring a single procedure with maximal efficacy should be counseled on the advantages of a ureteroscopic approach.

When the ureteral orifice is too narrow to accommodate the ureteroscope, dilation may be accomplished with serial dilators, balloons, or even the ureteroscope itself. The anatomy of male patients may not allow a rigid ureteroscope to be easily passed above the iliac vessels, but a flexible ureteroscope usually can be advanced over a guidewire. The entire ureter can be more easily accessed with a rigid ureteroscope in female patients. Once the stone is visualized, fragmentation with the lithotrite of choice is performed. Complete fragmentation to a size less than that of the safety wire diameter (0.035 inch) should allow passage of all fragments without sequelae. Alternatively, fragmentation to a size sufficient for extraction by a stone retrieval device achieves a stone-free state for the patient at the end of the procedure.

Multiple different devices exist to prevent stone retropulsion from the ureter into the kidney during lithotripsy. These antiretropulsion devices are covered extensively elsewhere in this textbook. Their overall benefit is seen with semirigid ureteroscopy when the surgeon wishes to avoid performing flexible nephroscopy of the kidney to retrieve any small fragments that may have traveled proximally at time of treatment of the ureteral stone. If ureteral edema or injury is present after stone extraction, a postureteroscopy stent should be placed to prevent colic and obstruction. Multiple meta-analyses have found that for uncomplicated ureteroscopy, a ureteral stent may be safely omitted (Nabi et al, 2007; Makarov et al, 2008; Pengfei et al, 2011). If the clinical situation does not allow primary ureteroscopy (sepsis, inability to advance the ureteroscope, ureteral injury, equipment failure), a ureteral stent is placed and the problem corrected. Secondary or post-stent ureteroscopy has the advantage of working through a dilated ureter, often allowing the use of larger rigid ureteroscopes.

Ureteral Access Sheath

The use of a ureteral access sheath as an adjunct to ureteroscopy was first reported by Takayasu and Aso in 1974 as a means to simplify access to the intrarenal collecting system. It was not until more than two decades later that the ureteral access sheath was rediscovered and refined, simplifying the deployment and safety of these devices. The present generation of ureteral access sheaths consists of a hydrophilic outer coating, as well as a tapered transition from obturator to sheath, which facilitates their retrograde placement. The walls of the sheaths are designed not only for a slim profile but also for strength and often are reinforced so as to resist kinking.

Kourambas and associates (2001) reported that the ureteral access sheath can be successfully deployed in over 90% of attempted placements. In this randomized controlled study these authors also found that the use of an access sheath decreased operating room time, simplified re-entry of the ureter, and, likely as a consequence of these two points, was associated with decreased operating room costs. In a larger, retrospective study from the same institution, L'Esperance and associates (2005) reported on a series of 173 patients undergoing ureteroscopy with an access sheath and compared these outcomes to those of 83 patients undergoing ureteros-

copy without an access sheath. They found that the stone-free rate was significantly higher when the access sheath was employed (79% vs. 67%; $P = .042$). Portis and associates (2006) also reported on a prospective series of patients undergoing ureteroscopy with a ureteral access sheath and commented that the sheath facilitated the active extraction of all stone fragments. Finally, ureteral access sheaths may have an added benefit when treating infection-related calculi, because the use of a sheath has been reported to maintain low intrapelvic pressures during ureteroscopy (Rehman et al, 2003). Additionally, as irrigating fluid drains through the access sheath external to the patient, the need for periodic emptying of the patient's bladder during a prolonged procedure is eliminated. However, potential drawbacks to the ureteral access sheath have been identified. Traxer and Thomas (2013) observed a 46.5% ureteral injury rate at time of ureteroscopy when a ureteral access sheath was used; however, in only 13.3% of cases was the injury deep enough to involve the ureteral musculature. Another study noted that not placing a stent after ureteroscopy with an access sheath was associated with a significantly higher postoperative pain score and higher likelihood of contact with a medical provider for pain (Torricelli et al, 2014).

Complications

As modern ureteroscopes have become smaller and less traumatic, as safer intracorporeal lithotripters have become widely available, and as a better understanding of the technical principles of ureteroscopy has been developed, the number of complications arising from the management of ureteral stones has been steadily decreasing.

Fortunately, most of the complications caused by ureteral stones and their management respond favorably to simple drainage of urine with ureteral catheters or stents. A study of 11,885 ureteroscopy procedures reported an overall complication rate of only 3.5%, with the most frequent complication being fever (1.8%) (de la Rosette et al, 2014).

Perforation. As is true with most ureteroscopic complications, the incidence of ureteral perforation has decreased over time, as technology and technique continue to improve. In a series of ureteroscopic procedures reported in 1992, ureteral perforation was reported in approximately 15% of cases. More recent series report a perforation rate of 0% to 4% (Preminger et al, 2007; Bader et al, 2012). A number of actions may result in a ureteral perforation; some of the more commonly encountered scenarios include the splitting of a ureter after balloon dilation, forceful placement of ureteral access sheath, or a traumatic injury from forceful and misdirected manipulation of a stone. In some cases an intracorporeal device such as a lithotrite or electrocautery can cause full-thickness damage to the ureter. The incidence of ureteral perforation varies among the different intracorporeal lithotrites, with the highest incidence of ureteral perforation occurring with EHL. Baskets and grasping devices also may cause injury, because in the process of grasping a stone or lesion it is possible to inadvertently snare part of the ureter, which may result in a perforation. Traxer and Thomas (2013) observed a 46.5% ureteral injury rate at time of ureteroscopy when a ureteral access sheath was used; however, in only 13.3% of cases was the injury deep enough to involve the ureteral musculature. Finally, the pressurized irrigation can cause perforation or calyceal rupture.

Adherence to the tenets of safe ureteroscopy will minimize the likelihood of a ureteral perforation. Nonetheless, such a complication may still occur and it is important for the urologist to be familiar with the treatment of this event. **When a ureteral perforation is recognized, the ureteroscopic procedure should be terminated and a stent placed across the injury.** The risk for perforation underscores the importance of using saline as an irrigant, to prevent electrolyte derangements due to fluid extravasation. In cases of a severe injury, with significant extravasation of fluid, a percutaneous nephrostomy drain also may be necessary. Urinoma can result from perforation as well and may need to be drained. Antibiotics should be given because of the risk for infected urine and abscess

formation. In general, a stent should be left in place for approximately 4 weeks after injury. Subsequent imaging after ureteral stent removal is mandatory, to evaluate for a proper healing and adequate drainage.

Schuster and associates (2002) found a significant association of ureteral perforation with increased operative time. This suggests that if the procedure is difficult and not progressing, it is wise for the urologist to stop, place a stent, and plan for a staged procedure. The best prevention strategies are similar to the principles discussed earlier, including controlled maneuvers without force, knowing the margin of safety of the equipment being used, and always using both a working and safety guidewire.

Stricture. The development of a postoperative ureteral stricture is one of the more serious complications that may occur after ureteroscopy. Approximately two decades ago, the reported incidence of ureteral stricture after ureteroscopy was as high as 10%. More recently, however, the incidence of a postoperative stricture is reported to be 3% to 6% (Preminger et al, 2007) and in one review as low as 0 to 0.2% (Bader et al, 2012). It is likely that the improvements in surgical technology and technique are responsible for this dramatic reduction.

Although the cause of a ureteral stricture is likely multifactorial, certain factors have been reported to increase patient risk for stricture development. Roberts and coworkers (1998) reported a 24% stricture rate for stones that had been impacted an average of 11 months. Impacted stones are defined by the inability to pass a wire or catheter beyond the stone or stones that have been present and not moved for 2 months or more. Meng and coworkers (2003) reported that a ureteral perforation also may increase the risk for stricture formation, finding that strictures occurred in 5.9% of patients who suffered a ureteral perforation during ureteroscopy. It may be that an inflammatory response that results in devascularization and ischemia promote this process, because such local changes can result in a cicatrization of the ureter. Patients with a history of ureteral surgery, pelvic radiation, and impacted stones are also at greater risk secondary to altered blood flow and poor healing. Devascularization injury can result in ureteral necrosis, which necessitates open or laparoscopic repair. However, some patients develop a ureteral stricture in the presence of no intraoperative misadventures, suggesting that there is much about this process that remains to be elucidated.

To reduce the risk for stricture, care should be taken during all parts of the procedure, because the traumas that may increase the risk for this event are many and varied. **Overly aggressive manipulation of a ureteroscope across a narrow segment of ureter, as well as trauma or perforation from injudicious manipulation of intracorporeal devices or lithotrites may increase the risk for stricture.** Because of the reported occurrence of a postoperative ureteral stricture even after an uncomplicated ureteroscopy, it is recommended that all patients undergo postoperative imaging after ureteroscopic instrumentation to ensure that such a complication is recognized. Although most patients with a stricture will be symptomatic, between 0.4% to 4% will be entirely asymptomatic (Bugg et al, 2002; Weizer et al, 2002; Karadag et al, 2008), so imaging is recommended by the AUA in all patients to exclude such cases of silent obstruction (Fulgham et al, 2013).

The management of a postureteroscopic ureteral stricture will depend primarily on its length and location, although other factors such as the time elapsed since injury, nature of trauma, and patient-specific parameters merit consideration. For many short strictures, endoscopic management may be appropriate, and incision and dilation may yield a good result. For longer strictures, however, ureteral reconstruction can be more complex, requiring either open or laparoscopic repair. The types of reconstruction available are essentially the same as those for ureteral avulsion. If a stricture is short but has failed endoureterotomy, a ureteroureterostomy may be possible after the affected portion has been resected.

Submucosal Stone and Lost Stone. The submucosal stone and the lost stone represent two points on a continuum of iatrogenic displacement of a ureteral calculus into the wall of the ureter. Extrusion of a urinary calculus may occur in up to 2% of ureteroscopic

procedures. When the stone migrates only to the submucosa, a problematic complication can develop, because removal of such stones is difficult. If submucosal stones are encountered, laser excision followed by ureteral stent placement is recommended. Submucosal stones are of concern, because they can increase the risk for ureteral stricture formation.

Complete extrusion of a calculus, also known as a lost stone, can occur in the setting of a ureteral perforation. In most cases, if the fragment is completely outside the collecting system it can be left in place. Attempts to retrieve the stone may exacerbate the injury and increase the risk for significant irrigant extravasation. When an extruded stone is recognized, the procedure should be terminated and a ureteral stent placed. Antibiotics should be administered to prevent the theoretical risk for abscess formation, although such a complication would be rare. One of the most serious sequelae of such an event is the later development of a ureteral stricture; for this reason patients who have calculus extrusion should undergo postoperative imaging, which will confirm the stone location. It is possible that, in the future, the lost stone could be confused for a ureteral stone, and it is important for the patient to be aware that such a situation exists.

Avulsion. Perhaps the most catastrophic complication that can occur during a ureteroscopic procedure is avulsion of the ureter. Fortunately, such a complication is a rare occurrence, reported in less than 0.06% to 0.5% of all cases (Bader et al, 2012); in fact, a review of over 1000 patients undergoing ureteroscopy reported no episodes at all of ureteral avulsion (Krambeck et al, 2006b). **Ureteral avulsion generally occurs as a consequence of overly forceful manipulation of a large or impacted calculus; however, a scabbard effect also can be created with resulting avulsion at time of scope withdrawal if too large a rigid ureteroscope is forcefully advanced up the ureter.** It has been reported that the proximal third of the ureter may be at greatest risk for avulsion, because it is the portion of the ureter that has the least muscular tissue support. A ureteral avulsion is usually diagnosed when a portion of the ureter is withdrawn from the patient, along with the stone and basket or grasper.

There are a number of maneuvers the urologist can undertake to avoid a ureteral avulsion. **Blind basketing, the removal of a ureteral calculus without the aid of endoscopy, may increase the risk for ureteral avulsion and should never be considered an appropriate method of stone extraction (Preminger et al, 2007).** In fact, even endoscopically guided basketing should be reserved for small stones only. In general, a safe ureteroscopic procedure relies on the placement of both safety and working guidewires. **Before engaging a stone in a basket or grasping device, it should be endoscopically evaluated to determine if it is of a size that would be likely to be extracted out of the ureter.** When the stone is engaged in the basket or grasper, the stone and device should both be kept under direct vision as they are extracted, so that the size of the stone can be continually compared with the size of the ureteral lumen. If the stone appears to be too large to be removed intact, it should be fragmented into smaller pieces that may either pass spontaneously or be extracted. If a stone too large to pass through the ureter is inadvertently engaged with a basket or grasping device, it should be released or replaced more proximally. If it is not possible to release the stone, the basket should be disassembled and the ureteroscope passed alongside the basket and the entrapped stone fragmented in situ. The use of a grasping device, rather than a basket, may simplify the release of an entrapped stone. The great benefit of having a safety wire in place is that should a stone become entrapped in the ureter a ureteral stent may be placed that will passively dilate the upper urinary tract and perhaps permit a more straightforward procedure at a later date.

Should a ureteral avulsion occur, a reasoned and considered approach to the management of the affected patient is advised. Although it may be tempting to perform an immediate primary repair at the time of injury, in general a delayed repair is recommended. The patient should undergo immediate diversion of the renal unit with the placement of a percutaneous nephrostomy drain. In some cases, a urinoma may develop as a consequence of

urinary extravasation; these collections are generally amenable to percutaneous drainage. Subsequent ureteral reconstruction techniques depend on the location of the injury and the amount of viable ureter that remains. For extensive injuries the treatment options are generally limited to ileal interposition (ileal ureter) or renal autotransplantation. Although a transureteroureterostomy may be a replacement option for some patients who have a ureteral injury, this repair technique is contraindicated in stone formers. For a more distal ureteral injury, a ureteral reimplantation with either a psoas hitch or Boari flap also may be successful. Nephrectomy has been reported to be an option for these patients as well; however, given the recurrent nature of stone disease and the fact that stone formers may be at increased risk for hypertension and diabetes, this approach is controversial.

Ureteroscopic Management of Intrarenal Calculi

Over the previous two decades, advances in fiberoptic technology have facilitated the development of practical flexible ureteroscopes; concomitant improvements in flexible intracorporeal lithotripters as well as intracorporeal grasping devices have promoted the use of flexible ureteroscopes for the treatment of renal calculi with a high degree of success. A study of 11,885 patients at 114 centers found that 25.2% of ureteroscopic procedures were performed for renal calculi (de la Rosette et al, 2014). Fuchs and Fuchs (1990) reported the first large series of patients with renal calculi who were treated by flexible ureteroscopy. In all cases, flexible ureteroscopy was performed after a 1- to 2-week period of ureteral stent placement. The overall stone-free rate was 87%, and the only complications reported were two cases of sepsis. The subsequent introduction of more miniaturized, flexible, actively deflectable ureteroscopes (7.5 Fr) has permitted the majority of ureteroscopic procedures to be performed without routine ureteral dilation. In two large series of patients with renal stones who underwent treatment with holmium laser lithotripsy, ureteral dilation was necessary in only 31% (Sofer and Denstedt, 2000) and 33% (de la Rosette et al, 2014) of patients. Numerous baskets and graspers now allow full deflection of flexible ureteroscopes, facilitating treatment of often difficult-to-access lower pole stones (Lukasewycz et al, 2004; Pearle et al, 2005).

As ureteroscopic technology has advanced, and as surgeons have gained increasing comfort with this technique, ureteroscopic lithotripsy intervention has become an increasingly common treatment for patients with renal calculi. Single session success rates, generally defined as successful fragmentation with complete stone clearance or the presence of "clinically insignificant" residual fragments, are reported to be in the 70% to 80% range (Mariani, 2007; Ricchiuti et al, 2007; Breda et al, 2008). However, when CT imaging is used to assess stone-free results range from 62% to 84% and vary based on the size of the renal stone (Portis et al, 2006; Macejko et al, 2009; Rippel et al, 2012). Success rates may be improved for larger stones if a secondary procedure is performed (Hyams et al, 2010). Even the treatment of staghorn calculi has been described, although this is not a widely used technique (Mariani, 2007). Complication rates are low, with fever and UTI being the most commonly encountered adverse events.

Technique

Proximal ureteral and intrarenal calculi can be accessed with actively deflectable, flexible ureteroscopes. Although, historically, a ureteral stent was left indwelling before ureterorenoscopy, this maneuver is currently necessary only when difficulty is encountered introducing the flexible ureteroscope into the ureter. If necessary, the stent is left for 2 to 4 weeks before the procedure (Erhard et al, 1996). The use of small-diameter ureteroscopes minimizes the necessity of ureteral dilation for stone access and may decrease associated morbidity. In cases of multiple stones or large stone burden requiring multiple passages of a basket, a ureteral access sheath may facilitate stone removal. A comparative study of ureteroscopic lithotripsy with or without access sheath showed that operative time was significantly

reduced by use of the access sheath, despite a greater mean stone burden in the access sheath group (Kourambas et al, 2001).

When a retrograde ureteroscopic approach is used to treat patients with intrarenal calculi, two wires are placed initially. The flexible ureteroscope is passed over one working wire in a monorail fashion. Saline is used for irrigation. When an implement is present within the working channel, simple gravity irrigation is inadequate and pressurized irrigation is required. The holmium:YAG laser lithotripter is used in almost all cases. Stones in lower pole calyces can be treated in situ or moved, with flexible graspers or a basket, into a position that allows better visualization. A head-down patient position with the ipsilateral flank elevated may help with stone and fragment visualization because fragments tend to migrate superiorly and are thus more easily localized during treatment. When access into the lower pole is difficult, prone positioning of the patient with the head down 20 degrees has been shown to provide the broadest angle of entry to the lower pole infundibulum (Bercowsky et al, 1999). The goal of holmium laser lithotripsy is to reduce the stone to fine dust and to small fragments 2 mm or less in diameter. If the stone is large, the collecting system often may become lined with fine dust and debris, which can obscure residual stones. Furthermore, poor visualization may lead to perforation. In such cases, either the irrigant in the intrarenal collecting system may be aspirated through the ureteroscope or a ureteral stent can be placed and the situation approached in a staged fashion.

Fragmentation of stones in situ in the lower pole can be challenging. If the lower pole infundibulum is accommodating, the most straightforward way to treat the stone is to engage it in a nitinol basket and displace it to the renal pelvis or an upper pole calyx. In this way it is generally a straight passage of the scope, with minimal deflection of the tip, which will simplify ureteroscopic laser lithotripsy. Residual fragments also should be more likely to evacuate spontaneously from the kidney.

Open Stone Surgery

Historically, most patients with symptomatic upper urinary tract calculi underwent open surgical lithotomy. Those patients with a small-to-moderate stone burden typically underwent pyelolithotomy, radial nephrolithotomy, or ureterolithotomy. For patients harboring staghorn calculi, more extensive procedures were required, including anastrophic nephrolithotomy, extended pyelolithotomy combined with radial lithotomies, and bench surgery with autotransplantation. However, the introduction of SWL and the development of endourologic techniques for stone removal have dramatically diminished the role of open stone surgery, especially for stone removal procedures, and open surgery is now one of the least common treatments of patients harboring upper urinary tract calculi. Turney and colleagues (2012) reported an 83% reduction in the number of open stone procedures performed from 2000 to 2010. Matlaga and Assimos (2002) reported that of 986 surgical procedures for stone removal performed at their institution between 1998 and 2001, 0.7% were open surgical procedures. Others have reported similar findings (Table 54-2), with an incidence of open stone surgery ranging from 0.3% to 5.4% (Assimos et al, 1989; Segura, 1990; Kane et al, 1995; Paik et al, 1998).

Renal Calculi

Minimally invasive techniques have clear advantages over open surgical techniques for patients harboring small-to-moderate burdens in otherwise normal kidneys. In 1985, Brannen and associates retrospectively compared PNL and open surgery for the treatment of patients with renal and proximal ureteral stones. Although the overall stone-free rate was similar, those patients treated by PNL experienced a shorter hospital stay, a lower narcotic requirement, and a shorter recovery period. Preminger and associates (1985) compared 88 patients undergoing PNL with 41 patients undergoing open stone surgery and found that PNL was associated with lower postoperative morbidity, more rapid convalescence, greater satisfaction of the patient, and reduced hospital costs for stones smaller

TABLE 54-2 Open Stone Surgery in the Modern Era

	ASSIMOS ET AL, 1989	KANE ET AL, 1995	PAIK ET AL, 1998	MATLAGA AND ASSIMOS, 2002
No. of open stone surgery cases (% of total stone removal procedures)	37 (4.1)	25 (3.13)	42 (5.4)	7 (0.7)
Stone-free rate (%)	100	71	93	100
INDICATIONS (%)				
Complex stone burden	3 (8.1)	3 (12)	23 (55)	0
Endoscopic treatment failure	18 (49)	51 (20)	12 (29)	1 (14)
Anatomic abnormality or concomitant open surgery	13 (35)	8 (32)	11 (46)	6 (86)
Body habitus	5 (14)	5 (19)	4 (10)	0
Other	2 (5)	6 (24)	4 (10)	0

than 2.5 cm. [Brown and associates \(1986\)](#) also demonstrated that PNL is more cost-effective than open stone surgery because of its reduced morbidity.

A more controversial issue has been the treatment of patients harboring staghorn calculi, a condition that carries a significant risk for mortality if it is untreated. [Boyce and Elkins \(1974\)](#) established anatomic nephrolithotomy as a standard treatment of patients with staghorn stones in the United States. Overall, the reported stone-free rate after open surgery for struvite calculi is approximately 85%, with a 30% stone recurrence rate over 6 years ([Griffith, 1978](#)). In comparing results for a combination of PNL and SWL with reported results of anatomic nephrolithotomy, [Kahnoski and associates \(1986\)](#) reported stone-free rates (85%) similar to those for the open surgical procedures, although convalescence and hospital stay for PNL were shorter and blood loss was less.

[Snyder and Smith \(1986\)](#) compared PNL with anatomic nephrolithotomy for patients with staghorn calculi. They reported that although the retained stone fragment rate was higher for PNL than for anatomic nephrolithotomy (13% vs. 0%), shorter procedure times, reduced need for blood transfusions and narcotics, and far more rapid return to work were achieved with PNL.

A meta-analysis undertaken by the AUA documented stone-free rates of 81.6% for open stone surgery, 80.8% for combined PNL and SWL, 73.3% for PNL, and only 50% for SWL monotherapy ([Segura et al, 1994](#); [Preminger et al, 2005](#)). The more invasive the procedure, the greater is the stone-free rate; however, morbidity was higher as well. Although SWL carried the lowest morbidity, a greater number of unplanned post-treatment interventions were necessary. The AUA concluded that for most patients, neither SWL monotherapy nor open stone surgery should be the first-line treatment of staghorn stones. As a guideline, PNL, followed by SWL or repeated PNL procedures as warranted, should be used for most patients with struvite staghorn calculi.

There are no strict guidelines that define which patient should undergo an open surgical procedure for stone removal. Some indications, such as a stone burden too large for PNL, clearly rely on the surgeon's judgment and experience and the availability of equipment. Also, those patients harboring calculi that may require multiple PNL or SWL treatments may be good candidates for an open procedure. Although a single open surgical procedure may seem to be the optimal procedure in the short term, the inevitable scar tissue that develops will compromise any future stone removal procedures. A small group of patients whose conditions are refractory to PNL, SWL, and ureteroscopy may require an open surgical procedure as a salvage technique.

Nephrectomy remains an option for patients with nonfunctioning kidneys or stone disease with a normal contralateral kidney. Partial nephrectomy is also an option for a stone in a localized area of irreversibly poor function. In addition, patients with an associated anatomic abnormality requiring open operative intervention, such as UPJ obstruction and infundibular stenosis, may be candi-

dates for an open surgical approach. Some patients requiring open surgery unrelated to their urologic problem also may benefit from a simultaneously performed open procedure.

Ureteral Calculi

Although ureterolithotomy has been a time-honored technique for many decades, it is seldom performed in the modern, endourologic era. A meta-analysis undertaken by [Segura and associates \(1997\)](#) for the AUA demonstrated median stone-free rates of 87% and 90% for stones in the distal ureter treated by open surgical removal and ureteroscopy, respectively. In the proximal ureter, the stone-free rate for ureterolithotomy was 97% compared with 83% and 72% for SWL and ureteroscopy, respectively. Although the results of open surgery in the proximal ureter in this historic analysis were somewhat better than those of minimally invasive techniques, the greater morbidity and longer hospitalization associated with open surgery favored a primary endourologic solution for ureteral stones. Further miniaturization of ureteroscopes, combined with the now widespread availability of the holmium:YAG laser, has increased the success rate for a ureteroscopic approach to proximal ureteral calculi. [Grasso and Bagley \(1998\)](#) reported a large series of patients undergoing ureteroscopy for proximal ureteral calculi, finding a 97% stone-free rate. Open surgery for patients with ureteral stones is now indicated only as a salvage procedure, when a planned abdominal operation coincides with a symptomatic ureteral stone episode, or when another ureteral abnormality requires open surgical repair.

Laparoscopic and Robotic Stone Removal

The surgical technique and outcomes of laparoscopic and robotic stone surgery are discussed in subsequent chapters; the focus of the following section is a brief overview of the role of laparoscopic and robotic procedures in the modern era of stone surgery. The advent of laparoscopic and subsequently robotic renal and ureteral stone removal procedures has provided the urologist with another means to circumvent open stone surgery. Every type of "lithotomy" procedure by use of a laparoscopic or robotic approach has been reported ([Raboy et al, 1992](#); [Winfield et al, 1993](#); [Ruckle and Segura, 1994](#); [Van Cangh et al, 1995](#); [Harmon et al, 1996](#); [Goel and Hemal, 2001](#); [Deger et al, 2004](#); [King et al, 2013](#)). However, because of higher morbidity and longer hospitalization a laparoscopic or robotic approach to stone removal should be considered only if the results with SWL or endoscopic approaches are expected to be poor ([Preminger et al, 2005, 2007](#)).

In certain cases a laparoscopic or robotic approach may be considered a reasonable therapy. Situations that may benefit from a laparoscopic approach include pyeloplasty with pyelolithotomy; patients harboring stones in poorly functioning polar areas or with nonfunctioning kidneys; pelvic kidneys containing a large stone

volume, in which laparoscopic techniques can be used to reflect overlying bowel, allowing pyelolithotomy or percutaneous stone removal; and ureterolithotomy for the extremely rare endoscopic failure or large/multiple impacted ureteral calculi. Case series of robotic and laparoscopic anastrophic nephrolithotomy have been published (Zhou et al, 2001; Simforoosh et al, 2008; Giedelman et al, 2012; King et al, 2013). Stone-free results range from 28% to 91%, and warm ischemia is used. It must be recognized that such procedures can be technically demanding and require a skilled laparoscopic/robotic surgeon to be performed with minimal morbidity. In present practice, the use of laparoscopy and robotics in the treatment of renal calculi continues to be limited; Desai and Assimos (2008) reported that only 1% of patients undergo such an approach, with the most common indication being renal stones with a concomitant UPJ obstruction.

KEY POINTS: STONE REMOVAL—SURGICAL TECHNIQUES AND TECHNOLOGY

- The holmium:YAG laser is one of the safest, most versatile, and most effective intracorporeal lithotripters and has become the standard lithotrite for the ureteroscopic approach.
- For patients undergoing PNL, a rigid lithotripter, such as a combination ultrasonic/ballistic device, will provide for more efficient stone removal than will a flexible lithotripter.
- For PNL, the preferred point of entry into the collecting system is along the axis of the calyx, through the papilla.
- The role of open, laparoscopic, and robotic stone surgery remains limited to unique cases in which the stone burden or patient anatomy precludes successful endoscopic treatment.

URINARY CALCULI DURING PREGNANCY

Incidence

Urolithiasis is an infrequent complication of pregnancy. However, pain from renal colic is the most common nonobstetric reason for hospital admission during pregnancy (Rodriguez and Klein, 1988). Furthermore, the occurrence of urinary calculi during pregnancy presents danger not only to the mother but also to the fetus because renal colic, infection, and obstruction are all associated with premature labor (Maikranz et al, 1987; Hendricks et al, 1991). The reported incidence of symptomatic urinary calculi during pregnancy ranges from 1 in 200 to 1 in 2500 pregnancies; the wide variation in reported incidence may be due to the small numbers of patients in these studies (Gorton and Whitfield, 1997). However, the incidence of symptomatic urinary calculi has been calculated to be the same for pregnant women as for nonpregnant women of childbearing age (Coe et al, 1978; Hendricks et al, 1991). Multiparous women have been reported to be affected more often than primiparous women, in some cases by a ratio of approximately 3:1 (Horowitz and Schmidt, 1985; Rodriguez and Klein, 1988). However, when it is adjusted for age, the incidence for multiparous women is no greater than that for primiparous women (Swanson et al, 1995). Calculi present with equal frequency on the left and right sides, although ureteral calculi occur almost twice as frequently as renal calculi (Stothers and Lee, 1992; Parulkar et al, 1998). The majority of patients with symptomatic calculi present during the second or third trimesters but rarely during the first trimester (Denstedt and Razvi, 1992; Stothers and Lee, 1992; Swanson et al, 1995).

Although symptomatic urolithiasis may be an uncommon complication of pregnancy, renal colic during pregnancy is a serious concern because such an event may be dangerous to both the mother and the fetus. Swartz and associates (2007) analyzed the hospital discharge data from 1987 through 2003 in the state of Washington and found that women admitted for nephrolithiasis had a significantly greater (adjusted odds ratio 1.8) risk for preterm

delivery than women without stones. Lewis and associates (2003) also reviewed a large database comprising over 21,000 deliveries and found that of the 86 patients diagnosed with a stone during pregnancy there was an increased risk for preterm premature rupture of membranes (2.9% in patients without stones vs. 7% in those with stones). Preterm premature rupture of membranes, as the authors note, carries with it an increased risk for morbidity and mortality to the newborn.

Etiology

Pregnancy induces significant physiologic alterations, some of which affect the urinary system. The most remarkable anatomic change is the dilation of the renal calyces, pelvis, and ureters, which is usually evident by the first 6 to 10 weeks of gestation. Pregnancy-induced hydronephrosis is the most common cause of dilation of the urinary tract in pregnancy and may cause flank discomfort or even mimic renal colic. Upper tract dilation is seen in up to 90% of pregnant women by the third trimester and may persist for as long as 12 weeks postpartum (Boridy et al, 1996). The right ureter tends to be more dilated than the left, and the dilation rarely is observed distal to the pelvic brim (Schulman and Herlinger, 1975). Rarely, spontaneous rupture of the kidney may occur; if it does, it more commonly happens on the right side (MacNeily et al, 1991; Loughlin, 1994). Both humoral and mechanical factors have been implicated in the cause of hydronephrosis in pregnant women. Circulating progesterone, a humoral factor that is increased in pregnancy, causes relaxation of ureteral smooth muscle, reducing ureteral peristalsis. Paller and Ferris (1996) reported that dilation of the urinary collecting system can be reproduced in an animal model by the administration of estrogen and progesterone. However, recent evidence suggests that mechanical factors, in particular the gravid uterus directly compressing the ureters, are likely to be primary in the pathogenesis of this condition; women with an altered upper urinary tract in whom the ureter does not cross the pelvic brim, such as those with ileal conduit or renal ectopia, do not experience hydronephrosis during pregnancy (Rasmussen and Nielsen, 1988; Dafnis and Sabatini, 1992; Swanson et al, 1995). Although the exact cause of hydronephrosis of pregnancy is not yet well defined, most would agree that both mechanical and humoral factors play a role in the pathogenesis of this condition.

Other important physiologic changes in pregnancy include an increase in renal plasma flow, which induces a 30% to 50% increase in glomerular filtration rate. As a result of this physiologic alteration the normal ranges of serum creatinine and blood urea nitrogen are approximately 25% lower for the pregnant patient. Importantly, then, a serum creatinine value that is in the normal range for the nonpregnant population may actually represent a decrease in renal function for the pregnant patient (Paller and Ferris, 1996). The increase in renal plasma flow and glomerular filtration rate also increases the filtered loads of sodium, calcium, and uric acid, causing a state of hypercalciuria and hyperuricosuria (Boyle et al, 1966; Howarth et al, 1977; Gertner et al, 1986). Hypercalciuria is further exacerbated by the suppression of parathyroid hormone and the increase in circulating 1,25-dihydroxycholecalciferol produced by the placenta, which increases intestinal absorption of calcium. Twenty-four-hour urine chemistries performed among pregnant women have demonstrated that urinary pH is elevated in the course of pregnancy, most dramatically during the second trimester (Resim et al, 2006). However, these potentially lithogenic physiologic changes are offset by an increase in the excretion of urinary inhibitors, such as citrate and magnesium, as well as an increase in urine output (Biyani and Joyce, 2002). It has been postulated that metabolic alterations in the urine may contribute to the accelerated encrustation of ureteral stents during pregnancy (Denstedt and Razvi, 1992; Loughlin, 1994). Ross and associates (2008) reported that stones that occur during pregnancy are most commonly calcium phosphate in composition, a finding that may be explained by the relatively elevated urinary pH and hypercalciuria that occur in the pregnant state.

Evaluation

Although renal colic is the most common nonobstetric cause of abdominal pain in hospitalized pregnant women, the diagnosis of urolithiasis in the pregnant patient can be challenging; many of the usual manifesting signs and symptoms may be masked by the patient's gravid status. As gestation progresses, the perception and localization of pain may be altered. [Stothers and Lee \(1992\)](#) reported that 28% of pregnant patients ultimately diagnosed with an obstructing stone were initially, and incorrectly, diagnosed with appendicitis, diverticulitis, or placental abruption. For most patients, however, **the most common presenting symptom is flank pain, usually accompanied by either macroscopic or microscopic hematuria** and, in some cases, UTI ([Stothers and Lee, 1992](#)). Hematuria can occasionally occur in the normal course of pregnancy; however, hematuria without discomfort is unusual in a patient with stone disease ([Swanson et al, 1995](#)). It is particularly important to obtain a urine specimen for culture from these patients because pyuria commonly may be seen in the urinalysis of a pregnant patient, which diminishes the sensitivity of this test in detecting UTI ([Hendricks et al, 1991](#); [Houshiar and Ercole, 1996](#); [Parulkar et al, 1998](#)). A diagnosis of urinary calculi should be considered in evaluation of a pregnant patient who suffers from persistent UTI or infection with a urea-splitting organism. Other symptoms that may indicate urolithiasis include irritative voiding symptoms, chills, nausea, and vomiting. However, these symptoms also may occur with other intra-abdominal conditions so the urologist must maintain a high index of suspicion when examining these patients.

An important factor in the radiographic evaluation of pregnant patients with stone disease is the risk for ionizing radiation exposure to the fetus. The principal effects of irradiation on the fetus include teratogenesis, carcinogenesis, and mutagenesis. However, the risk associated with radiation depends critically on the gestational age and the amount of radiation delivered ([Biyani and Joyce, 2002](#)). **During the first trimester, the period of early organogenesis and rapid cell division, the embryo is sensitive to the effects of radiation** ([Swartz and Reichling, 1978](#)). Although the fetus has diminished sensitivity to the teratogenic effects of radiation in the second and third trimesters, such exposure may increase the risk for development of childhood malignant neoplasia ([Harvey et al, 1985](#)).

Because the radiation dose below which no deleterious effects on the fetus may occur has not been defined with certainty, it may be presumed that exposure to any level of radiation will carry some degree of risk. For this reason **ultrasonography has become the standard initial study in evaluation of the pregnant patient thought to be experiencing renal colic**. Unfortunately, it can be difficult to adequately visualize the ureter with ultrasound examination as well as to distinguish dilation of the ureter that may be associated with a normal pregnancy from ureteral obstruction because of calculus. [Stothers and Lee \(1992\)](#) reported that renal ultrasonography for the detection of calculi had a sensitivity of 34% and a specificity of 86%. [Butler and associates \(2000\)](#) similarly reported that ultrasonography diagnosed 60% of 35 women who were later proved to have nephrolithiasis. Several techniques have been recommended to improve the diagnostic capability of this technology. Color Doppler imaging allows the sonographer to differentiate the iliac artery and vein from the dilated ureter. [MacNeily and associates \(1991\)](#) reported that the use of this technique can distinguish a dilated infrailiac ureter, which was strongly correlated with ureteral obstruction. Color Doppler imaging also can demonstrate jets of urine expelled from the ureter into the bladder. [Deyoe and associates \(1995\)](#) reported that if there are no ureteral jets on the suspected side of obstruction, ureteral obstruction can be diagnosed with a sensitivity of 100% and a specificity of 91%. However, [Burke and Washowich \(1998\)](#) reported that there is variation in ureteral jet symmetry in later pregnancy and recommended the use of this technique with caution. Renal vascular resistance increases in the presence of acute obstruction, and duplex ultrasonography allows the quantification of this alteration by calculating the kidney's resistive index ([Ulrich et al, 1995](#)). [Shokeir and Abdulma-](#)

[about \(1999\)](#) prospectively evaluated 117 nonpregnant patients with ultrasonography; they reported that resistive index measurements had 77% sensitivity and 83% specificity in diagnosis of ureteral calculi and that change in resistive index had 88% sensitivity and 98% specificity. [Horrigan and associates \(1996\)](#) reported that renal resistive index remains unchanged from the nonpregnant state throughout the course of pregnancy and also is unaffected by the physiologic hydronephrosis of pregnancy, which suggests that this imaging modality may be useful in detecting acute obstruction in this population. [Shokeir and associates \(2000\)](#) evaluated pregnant women in a manner similar to their initial study and found that resistive index had a sensitivity of 45% and a specificity of 91% in detecting an obstructing ureteral calculus; change in resistive index had a sensitivity of 95% and a specificity of 100%. If an obstructing calculus cannot be visualized by conventional renal sonography, **transvaginal ultrasonography can provide imaging of the distal ureter**. [White and associates \(2013\)](#) performed a multicenter longitudinal study of imaging modalities to detect stone in pregnant women ([White et al, 2013](#)). Importantly, they found that 14% of women undergoing intervention for a radiographically detected stone ultimately were found to harbor no such stone.

If the clinician determines that ultrasound evaluation is inadequate, other imaging studies may be considered. **If intravenous pyelography is required, a limited study is recommended**. [Stothers and Lee \(1992\)](#) were able to visualize calculi in 16 of 17 pregnant patients with a three-film study, obtaining scout, 30-second, and 20-minute films. Nuclear renography is a technique that can provide a functional assessment of pregnant patients with suspected ureteral obstruction while exposing them to a limited amount of radiation. However, the radioisotope is excreted in the urine, and the bladder reservoir can provide a significant source of radiation exposure to the fetus, necessitating high fluid intake and frequent voiding for these patients ([Biyani and Joyce, 2002](#)). This radiographic technique unfortunately does not provide good anatomic detail or visualization of calculi. Magnetic resonance imaging (MRI) does not rely on ionizing radiation or contrast medium, making it a potentially attractive tool to evaluate pregnant patients. Because MRI does not visualize calcium, stones are seen as filling defects overlying the high signal intensity of urine ([Fig. 54-24](#)). The visualization of smaller stones with this technique is difficult ([Hattery and King, 1995](#); [Roy et al, 1995](#)). [Spencer and associates \(2004\)](#)

Figure 54-24. Magnetic resonance urogram from a pregnant woman with right renal colic, demonstrating a right ureteropelvic junction stone as a filling defect in the bright, T2-weighted urinary collecting system.

reported on the use of MRI to evaluate pregnant women with hydronephrosis and flank pain and found that this technique enabled the accurate distinguishing of physiologic hydronephrosis of pregnancy from hydronephrosis resulting from an obstructing ureteral calculus. Mullins and associates (2012) also described a half Fourier single-shot turbo spin-echo (HASTE) MRI protocol that increased the utility of MRI in the evaluation of pregnant women. White and associates (2007) reported on a technique of low-dose radiation exposure CT for the evaluation of pregnant women; however, at present the reliability of low-dose CT in the diagnosis of urinary calculi is unresolved. **Conventional CT should be avoided during pregnancy because the radiation dose is particularly high.**

Treatment

Of pregnant patients with symptomatic calculi, 50% to 80% will pass their stones spontaneously when treated conservatively with hydration and analgesia (Denstedt and Razvi, 1992; Stothers and Lee, 1992; Gorton and Whitfield, 1997; Parulkar et al, 1998). Intervention is required in approximately one third of patients, usually for pain uncontrolled by analgesia or signs of persistent obstruction and infection. When treatment is selected, it should be recognized that there is some controversy regarding the most appropriate method of intervention. Some have maintained that ureteral stents are the optimal treatment of such patients. Although ureteral stents do effectively drain an obstructed collecting system, they are by no means the perfect solution to this problem. The changes in urinary chemistry that occur during pregnancy, in particular the hypercalciuria and hyperuricosuria, have been implicated in the accelerated encrustation of ureteral stents that is encountered in this population. As a consequence of this phenomenon it has been recommended that ureteral stents placed in pregnant women be exchanged every 4 to 6 weeks. Ostensibly, then, for a woman in an early gestational stage, multiple stent changes will be required over the course of the pregnancy. An indwelling stent places these women at an increased risk for bacteriuria, UTI, and stent migration, all of which are serious morbidities that may have an adverse effect on the pregnancy. Ureteral stents themselves are associated with pain, which can have a negative impact on a patient's quality of life.

Percutaneous nephrostomy drains are an alternative treatment option for pregnant women with obstructing renal calculi. Just as with ureteral stents, nephrostomy tubes will effectively drain an obstructed collecting system. However, many of the same limitations that apply to ureteral stents also apply to nephrostomy drains. Khoo and associates (2004) reported that of 29 pregnant women managed with nephrostomy drainage, over half required tube exchanges, replacements, or flushings that were required because of either dislodgement or obstruction. Kavoussi and associates (1992) also reported that the majority of pregnant patients managed with nephrostomy drainage will require exchange of the tube because of occlusion from debris. One third of the patients in the series reported by Kavoussi and associates ultimately required nephrostomy removal as a result of recurrent drain obstruction, fever, or pain.

Both ureteral stent placement and nephrostomy drain placement are temporizing procedures that do not remove the obstructing symptomatic calculus. Therefore both of these interventions imply that in the postpartum period the mother will require a definitive procedure to remove the calculus. It may be hypothesized that one of the advantages of both ureteral stent and nephrostomy drain placement is that neither of these procedures requires a general anesthetic. However, many of the reports of ureteroscopy in pregnancy have described local anesthesia, regional anesthesia, or sedoanalgesia, all approaches that obviate the need for general anesthesia. It is likely that recent improvements in surgical technology may be responsible for the increased usage of ureteroscopy in the treatment of pregnant women. In recent years there have been great advances in both semirigid and flexible ureteroscopes. As recently as a decade ago, standard ureteroscope diameter ranged up to 11 Fr, in contrast to modern endoscopes that typically have a diameter of 6 to 8 Fr. Consequently, accessing all aspects of the renal collecting system in

a safe and expedient manner is now a straightforward endeavor that generally does not require ureteral dilation or other extraordinary maneuvers. The widespread use of intracorporeal lithotrites such as the holmium laser permits the safe and atraumatic fragmentation of calculi at any location. Improvements in flexible grasping devices have enhanced the efficiency of stone extraction.

Overall, complications in pregnant women undergoing ureteroscopy are uncommon. Semins and associates (2009) performed a meta-analysis of all reports of ureteroscopy of pregnant women to define the rate of complications in this population. They then compared the complication rate to the AUA/EAU Ureteral Stones Guidelines and found that there were no differences in the complication rates among pregnant and nonpregnant women undergoing ureteroscopy. Johnson and associates (2012) confirmed these findings as they reported a multicenter trial that examined ureteroscopy in pregnant women; a complication rate of 4% was found.

Other treatment modalities that are effective in the nonpregnant patient are not appropriate for this population. Although there have been reports of the inadvertent treatment of pregnant patients with SWL, with no adverse sequelae to the fetus, pregnancy remains a contraindication to this treatment modality (Chaussey and Fuchs, 1989; Frankenschmidt and Sommerkamp, 1998). PNL should be deferred until after birth because this procedure often requires prolonged anesthesia and radiation exposure.

KEY POINTS: URINARY CALCULI DURING PREGNANCY

- Ultrasonography is the standard initial imaging study in evaluation of a pregnant patient.
- Improvements in ureteroscopy technology now permit ureteroscopic access to and treatment of stones at any location in the collecting system of the pregnant patient.
- It is important to minimize ionizing radiation exposure to the pregnant patient during ureteroscopy by use of a below-table x-ray source and to shield the fetus with a lead apron placed below the patient.

Bladder Calculi

Prostatic Calculi

Urethral Calculi

Preputial Calculi

Lower urinary tract lithiasis is among the oldest of known human maladies, with an often dubious and barbaric legacy spanning the full course of recorded human history. Notable sufferers of lower urinary tract lithiasis include Isaac Newton, Benjamin Franklin, Francis Bacon, John Marshall, Peter the Great, Louis XIV, George IV, Boerhaave, Scarpa, and Napoleon Bonaparte and his descendants (Ellis, 1969; Khai-Linh and Segura, 2006).

Shattock (1905) described what might be the earliest known case of lower urinary tract stone disease, when excavation of gravesites in Egypt showed a 6.5-cm bladder calculus within the pelvis of the body of a 16-year-old boy, dating back to approximately 4800 BCE. Given that the methods of burial diverged from Egyptian tradition, little else about the background of the remains could be surmised.

Although little is known about the understanding and treatment of urinary lithiasis in ancient civilizations, it is apparent that the affliction was so commonplace by the 5th century BCE that it warranted specific mention in the works of the prolific Greek physician Hippocrates (Pardalidis et al, 2007; Herr, 2008). Perhaps the most famous instance is his proclamation within the oath bearing his name, stating “I will not cut for stone, even for patients in whom the disease is manifest; I will leave this operation to be performed by practitioners, specialists in this art” (Adams, 1938). Whether this was an early acknowledgment of the emerging field of urology or a caution for physicians to exclude themselves from the lowly butchery perpetrated by early lithotomists remains a matter of debate (Herr, 2008).

Vague descriptions of urinary stone extraction can be found in ancient texts of the Roman, Greek, Persian, and Hindu civilizations; however, the term *lithotomy* was not coined until 276 BCE by the Greek Ammonius, and the procedure was not described in detail until the writings of the Roman Cornelius Celsus nearly 300 years later in CE 20 (Pardalidis et al, 2007; Herr, 2008).

Accounts of the Celsian method of cystolithotomy conjure up terrifying images of harrowing, regularly fatal interventions in which the patient, generally a child no older than 14, would be bound or held fast to a table with his legs severely jackknifed and abducted to expose the perineum. One or two fingers would be inserted into the rectum to locate the stone and manually draw it down toward the bladder neck. The perineum was then incised widely with a chisel-like razor, rending the flesh until the bladder was entered, and the stone was then extracted using a forceps or a hook. If the patient were lucky enough to survive the operation before exsanguinating, the surgeon would leave this wound open, applying a dressing of oil-soaked wool or freshly killed and gutted fowl (Moore, 2005; Pardalidis et al, 2007; Trompoukis et al, 2007; Herr, 2008). Recovery was often as agonizing as the initial procedure, when leakage of urine through the wound proved excruciating for the young patient (Trompoukis et al, 2007). Infection, incontinence, impotence, and fistula formation were all-too-common

morbidities of the procedure, and nearly half of all patients died soon after the operation (Moore, 2005; Herr, 2008).

The grotesque and morbid nature of the procedure, however, hardly served to dissuade many sufferers of bladder stones from submitting themselves to the procedure. Galen and other notable physicians of the day began performing lithotomy, thereby legitimizing the procedure to some degree. In addition, midwives underwent instruction and education in the technique to offer treatment to female patients. By the Middle Ages the practice of lithotomy was a booming business, performed mostly by roving lithotomists of varying skill and competence who would ply their trade for a fee, performing the procedure on as many patients as possible before being driven out of town as their patients expired en masse (Herr, 2008).

Although small refinements were made to the procedure through the ensuing centuries, the practice of lithotomy remained largely unchanged for nearly 1500 years (Herr, 2008). In Paris during the early 16th century, Jacques de Beaulieu, a poorly trained and uneducated monk known more famously today as the subject of the children’s song “Frere Jacques” than as a pioneering surgeon of his time, refined the techniques of Pierre Franco using a lateralized perineal approach that proved a slightly less morbid operation. Although many surgeons of the time dismissed Frere Jacques as a quack, he became a prolific practitioner of lithotomy, providing his services to more than 5000 patients throughout Europe (Kelly, 1909; Bail, 1932; Moore, 2005; Herr, 2008). de Beaulieu’s methods were later adopted by William Cheselden, a Briton, who perfected the techniques of his forebears, introducing new instrumentation and an informed anatomic approach that reduced the mortality of lithotomy to less than 10% (Gross and Gross, 1876; Moore, 2005; Herr, 2008).

Fortunately, modern advances in surgical technology and aseptic technique have transformed this once deadly affliction into an eminently manageable and rarely fatal disease process. In addition, changing diets and the advance of industrialization have served to reduce significantly the incidence of lower urinary tract calculi, especially in the Western world.

BLADDER CALCULI

Bladder stones are the most common manifestation of lower urinary tract lithiasis, currently accounting for 5% of all urinary stone disease and approximately 1.5% of urologic hospital admissions in industrialized Western nations (Smith and O’Flynn, 1975; Schwartz and Stoller, 2000; Papatsoris et al, 2006). Bladder calculi in nonendemic areas are typically found in adults and are almost always associated with other disease processes resulting in urinary stasis or the introduction of a foreign body (Schwartz and Stoller,

2000). In endemic regions, however, bladder calculi often arise in children in whom major anatomic abnormalities do not coexist; in these regions, dietary intake and socioeconomic factors primarily influence the formation of bladder calculi (Andersen, 1962; Asper, 1984).

Primary Bladder Calculi

Formerly common in Europe and the United States, primary bladder calculi of childhood have been practically eliminated by the spread of industrialization and the modernization of the Western diet since the early 1900s (Van Reen, 1980; Schwartz and Stoller, 2000). However, childhood bladder lithiasis remains common in endemic regions, throughout a stone belt reaching from northern Africa, through the Middle East and the Balkans, and into India, Japan, Thailand, and Indonesia; it is uncommon in the southern hemisphere (Valyasevi and Van Reen, 1968; Valyasevi and Dhanamitta, 1974; Thalut et al, 1976; Asper, 1984; Teotia and Teotia, 1990; Hesse and Siener, 1997; Kamoun et al, 1999; Rizvi et al, 2003; Ali and Rifat, 2005). It is important to note that the term *primary* in this context refers to the fact that these stones develop in the absence of any known functional, anatomic, or infectious factors and the term does not necessarily imply that stones have formed de novo in the bladder (Andersen, 1962).

Primary bladder calculi are most common in children younger than the age of 10, with a peak incidence at 2 to 4 years of age (Valyasevi and Van Reen, 1968; Thalut et al, 1976; Teotia and Teotia, 1990; Ali and Rifat, 2005). The disease is much more common in boys than in girls, with ratios ranging from 9:1 to as high as 33:1 in areas of India (Andersen, 1962; Thalut et al, 1976; Van Reen, 1980; Kamoun et al, 1999; Rizvi et al, 2003). Stones are usually solitary and after removal they rarely recur (Valyasevi and Van Reen, 1968; Van Reen, 1980; Teotia and Teotia, 1990). Ammonium acid urate, calcium oxalate, uric acid, and calcium phosphate are the most common components of primary bladder calculi (Valyasevi and Van Reen, 1968; Teotia and Teotia, 1990).

Predisposition to the formation of bladder calculi appears to arise from a number of nutritional and socioeconomic factors. Children in endemic regions often consume a predominantly cereal-based diet that is poor in animal protein and low in phosphate (Thalut et al, 1976; Van Reen, 1980; Teotia and Teotia, 1990). In some regions, infant diets consist only of predigested rice that is first chewed by the mother, as well as breast milk, both of which are critically low in protein and phosphate (Andersen, 1962; Valyasevi and Van Reen, 1968; Thalut et al, 1976). Low dietary intake of phosphate not only leads to hypophosphaturia but also to hyperammonuria, promoting the precipitation of both calcium oxalate and ammonium acid urate (Teotia and Teotia, 1990). In addition, in the poor villages of Thailand, tampala and bamboo shoots, both of which are rife with bioavailable oxalate, are a frequent staple for infants (Valyasevi and Dhanamitta, 1974), which when combined with low dietary intake of vitamins B₁, B₆, and magnesium can lead to hyperoxaluria and the formation of calcium oxalate stones. Vitamin A deficiency can also lead to urothelial degeneration, which may also promote stone formation (Teotia and Teotia, 1990).

In addition, substandard living conditions and poor sanitation can lead to a paucity of adequate drinking water and to an increased prevalence of diarrhea, which in turn can lead to dehydration and supersaturation of stone-forming compounds in the urine (Valyasevi and Van Reen, 1968; Thalut et al, 1976; Van Reen, 1980; Schwartz and Stoller, 2000).

Children suffering from primary bladder calculi rarely present acutely. There is often a prodrome consisting of the passage of sandy urine or the presence of dusty crystals in dried urine that heralds the precipitation of urinary solutes. Children often complain of vague abdominal discomfort, dysuria, frequency, and hematuria. Pulling of the penis is considered by some to be pathognomonic, because it indicates the child is suffering from stranguria; frank urinary retention, however, is rare. In some cases, rectal prolapse and conjunctival hemorrhages may develop as the result of intense

straining to void (Thalut et al, 1976; Teotia and Teotia, 1990; Ali and Rifat, 2005).

Prevention consists mostly of dietary modification. In Thailand, phosphate supplementation was found to reduce oxalate crystalluria significantly, even without concomitant reduction in oxalate intake (Valyasevi and Dhanamitta, 1974). However, other authors suggest a transition to a mixed-cereal diet with milk supplementation as the most practicable solution for bladder stone prevention (Teotia and Teotia, 1990).

KEY POINTS: PRIMARY BLADDER CALCULI

- Primary bladder calculi are more common in children exposed to low-protein, low-phosphate diets.
- Primary bladder calculi rarely recur after treatment.

Secondary Bladder Calculi

Bladder calculi of the type commonly encountered throughout the Western world are typically found in men older than age 60 and are usually in concert with lower urinary tract obstruction, which prevents complete bladder emptying (Doudenias et al, 1991; Takasaki et al, 1995; Hesse and Siener, 1997; Yasui et al, 2008). Since the mid-1970s, the overall incidence of bladder calculi appears to have stabilized or decreased among males and increased slightly for females; these trends are likely caused by the increase in the size of the elderly population as life expectancies lengthen, as well as by an overall increase in the number of female genitourinary procedures performed annually (Schwartz and Stoller, 2000; Terai et al, 2008; Yasui et al, 2008).

Bladder calculi may arise de novo within the bladder or may result from the maturation of stone nidi that migrate from the upper tracts and subsequently fail to be voided spontaneously. The latter appears to be far less common than initially postulated, because only 3% to 17% of patients will report a history of renal colic to suggest the passage of a calculus from the upper tracts (Aird, 1957; Smith and O'Flynn, 1975; Doudenias et al, 1991). The frequent absence of calcium oxalate in the nucleus of most bladder stones further suggests against an upper tract origin (Doudenias et al, 1991; Vanwaeyenbergh et al, 1995). The pathogenesis and composition of bladder calculi depend largely on the inciting pathologic process and the presence or absence of infection.

Bladder Outlet Obstruction and Acquired Lower Urinary Tract Pathologic Process

Bladder outlet obstruction resulting in incomplete emptying and the retention of stone fragments is the most common predisposing factor for bladder stone formation in non-neurogenic bladders and is present in 45% to 79% of all patients diagnosed with vesical calculi (Smith and O'Flynn, 1975; Doudenias et al, 1991; Takasaki et al, 1995). In men, outlet obstruction is generally related to benign prostatic hyperplasia, whereas urethral kinking from a cystocele or pelvic organ prolapse is often the culprit in females (Smith and O'Flynn, 1975; Doudenias et al, 1991; Sarica et al, 1994; Nieder et al, 1998; Schwartz and Stoller, 2000; Papatsoris et al, 2006). Urethral stricture, bladder neck contracture, and bladder diverticula are also secondary causes that may interrupt normal voiding patterns (Smith and O'Flynn, 1975; Doudenias et al, 1991).

The composition of stones resulting from anatomic obstruction varies with geography and ethnicity. In Europe, struvite, calcium phosphate, and uric acid predominate, whereas in Japan uric acid calculi are uncommon and calcium stones are increasing in incidence, now representing 72% of all stones found in a recent series. Calcium oxalate comprises the majority of bladder stones found in the United States, although uric acid stones predominate among the American Jewish population (Smith and O'Flynn, 1975; Doudenias et al, 1991; Hesse and Siener, 1997; Papatsoris et al, 2006;

Yasui et al, 2008). Stones are usually solitary, although multiple stones may exist in 25% to 30% of patients (Sarica et al, 1994).

Intravesical Foreign Body

Foreign material within the bladder provides an ideal nidus for stone formation and is responsible for the majority of bladder calculi diagnosed in females (Smith and O'Flynn, 1975; Schwartz and Stoller, 2000; Papatsoris et al, 2006). Often a foreign body within the bladder will encrust initially with calcium oxalate as a result of the normal stasis that occurs with the storage of urine. Should infection supersede, rapid coalescence of the stone may occur as struvite is deposited on the nascent stone (Dalton et al, 1975; Khan and Wilkinson, 1990; Vanwaeyenbergh et al, 1995; Schwartz and Stoller, 2000).

The vast majority of intravesical foreign bodies result from iatrogenic interventions, although self-mutilation plays a role in a minority of patients (Dalton et al, 1975; Douenias et al, 1991; Schwartz and Stoller, 2000); complications resulting from urogynecologic interventions predominate. Inadvertent violation of the bladder with suture material during suspension or sling procedures is a common source of an intravesical foreign body. This error is often not detected intraoperatively, underscoring the importance of thorough cystoscopic inspection before the conclusion of the procedure (Zderic et al, 1988). Along with the rise in popularity of incontinence surgery involving synthetic mesh, such as tension-free vaginal tape procedures, an increase has been noted in calculi forming on portions of the mesh that have eroded into the bladder (Chamary, 1995; Koelbl et al, 2001; Irer et al, 2005; Mustafa and Wadie, 2007). In addition, erosion of wire suture used for cerclage has been reported (Ehrenpreis et al, 1986). Stone encrustation of migrated intrauterine devices, pessaries, and contraceptive diaphragms has also been reported (Staskin et al, 1985; Khan and Wilkinson, 1990; Mahazan, 1995; Chow et al, 1997; Maskey et al, 1997; Schwartz and Stoller, 2000; Demirci et al, 2003; Chae et al, 2012). In addition, unrecognized anorectal impalement, although an uncommon occurrence, has been reported to provide a foreign body nidus for bladder stone formation (Guha et al, 2012).

In men who have undergone radical retropubic prostatectomy, formation of stone on eroded silk sutures used to ligate the dorsal vein complex have been reported (Scheidler et al, 1990; Miller et al, 1992). Stones may also form on nondegradable surgical clips placed near the vesicourethral anastomosis that have migrated into the bladder; such stones have been reported with both metal and plastic clips, although the true incidence of this complication remains unclear (Banks et al, 2008; Kadekawa et al, 2009; Mora et al, 2010; Yi et al, 2010). In addition, necrotic tissue resulting from chemical ablation of the prostate for benign prostatic hyperplasia has been cited as a nidus for stone formation (Ikari et al, 2005), as has the presence of intraprostatic stents (Chiu et al, 1991; Squires and Gillatt, 1995). Migration of seeds following prostate brachytherapy is common and can be associated with bladder stone formation (Sugawara et al, 2009; Miyazawa et al, 2012; Leapman et al, 2014). Erosion of an inflatable penile prosthesis and artificial urinary sphincters resulting in stone encrustation has also been reported (Dupont and Hochman, 1988; Barroso et al, 2000; Bartolletti et al, 2000).

The development of bladder calculi is an infrequent complication of long-term urinary tract drainage. Encrustation of short-term ureteral stents is a common finding, although significant intravesical stone formation may occur in instances where the stent is left resident for an extended period (Giannakopoulos et al, 2001; Damiano et al, 2002; Hao et al, 2008; Vanderbrink et al, 2008; Waters et al, 2008). Long-term bladder drainage may also result in bladder lithiasis, with a reported incidence of 0.07% to 2.2% in patients with chronic indwelling catheters (Kohler-Ockmore and Feneley, 1996). In instances in which Foley balloons burst intravesically, retained fragments frequently lead to subsequent stone formation (Chute, 1962; Smith and O'Flynn, 1975). Even patients who perform clean intermittent catheterization may not be immune, because inadvertent introduction of hair into the bladder with the

passage of the catheter may provide a nidus for stone formation (Derry and Nuseibeh, 1997).

On rare occasions, intravesical calculi may also arise as a result of the migration and erosion of foreign bodies unrelated to genitourinary manipulation. These include orthopedic cement, surgical clips, ventriculoperitoneal shunts, and abandoned gallbladder stones resulting from spillage during cholecystectomy (Radford and Thomson, 1989; Chia and Ross, 1995; Maier and Treu, 1996; Eichel et al, 2002).

Neurogenic Bladder and Spinal Cord Injury

Neurogenic bladder resulting from spinal cord injury or myelomeningocele places patients at increased risk of bladder stone formation. For adults with spinal cord injury, the risk for bladder stone formation peaks at 3 months after the initial injury, and within 10 years 15% to 30% of patients will have formed at least one stone (Chen et al, 2001). Unfortunately, after a patient has formed one stone, the risk for subsequent stone formation quadruples (Ord et al, 2003). The level and severity of the spinal cord injury appears to be closely correlated with the risk of bladder stone formation, especially after the first year (Chen et al, 2001; Sugimura et al, 2008). This is possibly because of the inability of quadriplegics with complete cord lesions to perform intermittent catheterization themselves, relying instead on caretakers or a chronic indwelling catheter for bladder management (Sugimura et al, 2008).

Indeed the manner of bladder management in spinal cord injury appears to have a significant impact on the risk of stone formation. One large study of more than 450 patients noted that the use of clean intermittent catheterization was associated with a significant reduction in the risk of bladder stone formation, with an annual risk of 0.2%, compared with 4% in those patients managed by a chronic indwelling catheter (Ord et al, 2003). This finding has been corroborated by other reports (Mitsui et al, 2000; Chen et al, 2001). In addition, the use of clean intermittent catheterization is associated with a 40-fold decrease in the risk for hospital admissions as a result of bladder calculi (Ord et al, 2003). As such, clean intermittent catheterization is the recommended form of bladder management for all patients in whom it is feasible (Feifer and Corcos, 2008). However, for patients who must rely on chronic indwelling catheters, suprapubic cystostomy provides no benefit compared to urethral catheterization in terms of the development of bladder calculi, although patients often report greater satisfaction with the former (Ord et al, 2003; Sugimura et al, 2008).

The incidence of bladder calculi in children with neurogenic bladder is far lower than in adults, developing in only 5% to 8% of nonaugmented children performing clean intermittent catheterization. The incidence of bladder stones is slightly higher, however, in children who catheterize through a Mitrofanoff conduit than in those who catheterize per urethra (Barroso et al, 2000).

Bladder Calculi in Transplant Patients

Bladder calculi are uncommon complications of solid organ transplantation, occurring primarily in pancreatic allografts drained via the bladder. In all reported instances, nonabsorbable suture material or surgical clips have been found to serve as the nidus for stone formation (Hakim et al, 1997; Del Pizzo et al, 1998; Hahnfeld et al, 1998; Rhee et al, 1999; Schwartz and Stoller, 2000). Stone formation may be potentiated by low serum pH because of bicarbonate leak, as well by as urinary stasis and incomplete bladder emptying resulting from diabetic uropathy. When combined with an increased coincidence of bacteriuria caused by colonization of included duodenal segments and the effects of immunosuppression, the ideal milieu for calculus formation can arise (Rhee et al, 1999). The reported incidence of bladder calculi in pancreatic allograft recipients ranges from 0.5% to 10% (Hakim et al, 1997; Del Pizzo et al, 1998; Hahnfeld et al, 1998).

Bladder calculi may also occur after renal transplantation without simultaneous pancreatic transplant, with incidences ranging from 0% to 5% in the literature. In most instances, suture material serves

as the nidus for stone formation; however, although two studies identified the development of calculus material on absorbable polyglactin sutures, another large series showed that calculus formation only occurred in cases where nonabsorbable suture material had been used for the ureterovesical anastomosis (Leunissen et al, 1987; Klein and Goldman, 1997; Rhee et al, 1999; Lipke et al, 2004).

KEY POINTS: SECONDARY BLADDER CALCULI

- Secondary bladder calculi are generally associated with bladder outlet obstruction.
- Patients with spinal cord injury are at increased risk of bladder stone formation.
- Intermittent catheterization decreases the risk of bladder stone formation in comparison to an indwelling catheter.

Augmented Bladders and Urinary Diversion

Bladder and pouch stones are known complications of augmentation cystoplasty and urinary diversion. They arise from a complex interplay of functional, anatomic, metabolic, and infectious factors.

Bladder Augmentation

The reported incidence of bladder calculus after augmentation cystoplasty ranges from 10% to as high as 52.5% (Edin-Liljegren et al, 1996; Kaefer et al, 1998; Kronner et al, 1998; Bertschy et al, 2000; Mathoera et al, 2000; Madersbacher et al, 2003). Unlike traditional adult urolithiasis, females are more commonly affected than males, likely owing to the high incidence of cloacal abnormality requiring additional procedures beyond augmentation (Mathoera et al, 2000). Mean time to the formation of first stone ranges from 24.5 to 68 months, and after the first incidence the risk of recurrence is 19% to 44% (Blyth et al, 1992; Palmer et al, 1993; Kronner et al, 1998; Mathoera et al, 2000; Woodhouse and Lennon, 2001; DeFoor et al, 2004; Hensle et al, 2004).

Because bacteriuria and urinary tract infection are commonplace after augmentation cystoplasty, it is not surprising that the vast majority of associated calculi contain a significant struvite component (Blyth et al, 1992; Palmer et al, 1993; Kaefer et al, 1998; Hensle et al, 2004; Robertson and Woodhouse, 2006). Interestingly, however, struvite is not the predominant component in most infection-related stones found in augmented bladders; rather, one study showed a predominance of calcium phosphate in these stones, which is likely because of the lower pH required for precipitation of calcium phosphate as compared with struvite. In addition, up to 14% of patients were found to have noninfectious stones, consisting of calcium phosphate and calcium oxalate with no struvite component (Allison et al, 1985; Robertson and Woodhouse, 2006). Uric acid calculi are rare in augmented bladders (Blyth et al, 1992; Palmer et al, 1993; Hensle et al, 2004; Robertson and Woodhouse, 2006). The treatment of recurrent urinary tract infections with antibiotics might have the deleterious effect of eradicating *Oxalobacter formigenes* within the gut, leading to an increase in intestinal oxalate absorption and hyperoxaluria (Robertson and Woodhouse, 2006).

However, infection is just one aspect of the milieu that can lead to stone formation in augmented patients. As in nonaugmented bladders, urinary stasis and incomplete bladder emptying serve to potentiate bladder stone formation. Factors that might contribute to stasis include bladder neck reconstruction, artificial urinary sphincter placement, and urethral sling procedures, all of which are designed to provide hypercontinence (Kronner et al, 1998). In addition, catheterization through nondependent access, such as through Mitrofanoff channels, is associated with a higher risk of stone formation (Kaefer et al, 1998; Kronner et al, 1998; Barroso et al, 2000). Dehydration, hypocitraturia, hypercalciuria, as well as high urinary pH in intestinal augments may also contribute to stone formation (Woodhouse and Robertson, 2004).

The role of intestinal mucus in stone formation remains controversial. Bladder calculi are found almost exclusively in patients who have undergone augmentation cystoplasty with ileum or colon and are rarely encountered after augmentation using stomach or ureter or after autoaugmentation (Kaefer et al, 1998; Kronner et al, 1998; Bertschy et al, 2000; Mathoera et al, 2000; DeFoor et al, 2004; Woodhouse and Robertson, 2004). Although some cite the production of enteric mucus as a predisposing factor in bladder stone formation, both as a nidus for stone formation and as a promoter of bacterial biofilm formation (Bruce et al, 1984; Blyth et al, 1992; Khoury et al, 1997), others have challenged that notion. Three studies have evaluated the role of regular bladder irrigation to promote mucus washout; two found a significant reduction in the incidence of bladder calculi, suggesting that **mucus production has little effect on stone formation** (Brough et al, 1998; Mathoera et al, 2000). Another study, however, showed that the incidence of recurrent urinary tract infection could be reduced through a regular irrigation regimen, with a reduction of the incidence of bladder stones to less than 10% in augmented children (van den Heijkant et al, 2011). In addition, it has been suggested that the low urinary pH associated with gastric segments inhibits bacterial growth and the precipitation of struvite, thus explaining their decreased propensity for stone formation (Kaefer et al, 1998; Kronner et al, 1998). Indeed some of the few accounts of vesical stone formation after gastrocystoplasty have resulted in the administration of histamine blockade for patients, which raises the urinary pH (Kaefer et al, 1998).

Despite the apparent advantages of gastrocystoplasty as related to bladder stone formation, the use of the stomach includes significant comorbidity, such as hypokalemic hypochloremic alkalosis and hematuria-dysuria syndrome, and this comorbidity recommends against its routine use (Rink et al, 1995; Kronner et al, 1998).

Urinary Diversion

Similar to augmentation cystoplasty, urinary diversion using intestinal segments is associated with the formation of conduit and reservoir calculi, with incidences largely dependent on the type of diversion created. Calculi in incontinent diversions, such as ileal and colon conduits, are relatively uncommon. Despite early reports of a high rate of stone formation in ileal conduits created using stapler devices in several small series, the incidence in large modern experiences is low, ranging from 0% to 7.3% (Brenner and Johnson, 1985; Turk et al, 1999). Urinary stasis from stomal stenosis is believed to be a major predisposing risk factor in these cases, and, despite early concerns, encrustation of stone material on staple lines is not always the rule (Dunn et al, 1979; Brenner and Johnson, 1985; Madersbacher et al, 2003; L'Esperance et al, 2004).

Likewise the incidence of stone formation in both orthotopic neobladder and Indiana pouch diversion is low, ranging from 2.9% to 12.9% in modern series (Terai et al, 1996; Turk et al, 1999; Abol-Enin and Ghoneim, 2001; Deliveliotis et al, 2001; Beiko and Razvi, 2002). However, **patients who undergo continent diversion with a Kock pouch reservoir often do not fare as well, with incidences of pouch stone formation of up to 50%** (Ginsberg et al, 1991; Arai et al, 1993; Terai et al, 1996; Woodhouse and Lennon, 2001). Major contributing factors in the formation of Kock pouch calculi include exposed staple lines used to create the nipple valve, as well as the use of a nonabsorbable mesh collar. Elimination of the collar and the use of absorbable staples is associated with a significant reduction in the incidence of pouch calculi to as low as 10% (Ginsberg et al, 1991; Arai et al, 1993; Arif et al, 1999; Beiko and Razvi, 2002).

Struvite and calcium phosphate calculi predominate, indicating an infectious component in the development of most calculi in urinary diversions (Kaefer et al, 1998; Arif et al, 1999; Turk et al, 1999). In addition, patients with continent diversions were noted to have increased levels of urinary calcium, magnesium, and phosphate, as well as low levels of urinary citrate; metabolic acidosis might also occur. These metabolic derangements may further potentiate stone formation (Terai et al, 1995, 1996).

Presentation and Management

The most common presenting symptom of bladder calculi is macroscopic hematuria, which generally is terminal (Smith and O'Flynn, 1975; Papatsoris et al, 2006). Intermittency, frequency, urgency, dysuria, decreased force of the urinary stream, incontinence, and lower abdominal pain aggravated by brisk movement might also be present (Ellis et al, 1969; Smith and O'Flynn, 1975; Douenias et al, 1991; Miller et al, 1992; Sarica et al, 1994; Irer et al, 2005; Papatsoris et al, 2006). Larger stones tend to cause fewer symptoms, likely because of restricted movement within the bladder (Douenias et al, 1991). Bladder stones are rarely asymptomatic at the time of discovery (Smith and O'Flynn, 1975; Rhee et al, 1999).

The options for management of vesical calculi are varied. Any planned intervention should also aim to correct the underlying urinary tract pathologic process, when appropriate, to prevent stone recurrence.

Nonoperative Management

Chemical dissolution is rarely considered a primary form of management, because treatments are protracted and often do not address underlying functional or anatomic pathology. When administered properly, Renacidin is well tolerated and may be used to dissolve struvite and calcium phosphate calculi. This method involves the placement of a urinary catheter for continuous bladder irrigation of Renacidin solution. Alternatively, the solution can be administered intravesically 3 to 4 times daily and allowed to dwell for 30 to 45 minutes (Mulvaney, 1960; Mulvaney et al, 1960; Woodside and Crawford, 1980). Although effective for select patients, the use of Renacidin can be associated with catastrophic complications including death (Gonzalez et al, 2012). Great care must be taken to ensure that the patient remains free of any overt signs of systemic infection and that the catheter does not become obstructed. In addition, Renacidin is contraindicated in patients with renal insufficiency (Mulvaney et al, 1960; Wilson et al, 1986; Gonzalez et al, 2012). Uric acid calculi may be dissolved with oral administration of potassium citrate or intravesical administration of alkaline solutions (Asper, 1984; Rodman et al, 1984; Blyth et al, 1992; Drach, 1992; Menon and Resnick, 2002; Papatsoris et al, 2006). Irrigations with acetohydroxamic acid have proven effective in reducing the incidence of catheter encrustation in patients requiring chronic indwelling catheters (Burns and Gauthier, 1984).

Open and Percutaneous Cystolithotomy

Previously considered the gold standard for bladder stone treatment, the open approach has fallen into disfavor as newer, less invasive techniques have come to the fore. Open cystolithotomy, although successful, is associated with the need for prolonged catheterization, increased length of hospital stay, and poor cosmesis from the required incision (Bhatia and Biyani, 1994; Demirel et al, 2006). However, one group has reported on the successful implementation of drainless and catheterless open suprapubic cystolithotomy in children after meticulous two-layer closure of the cystotomy. After the procedure most patients were immediately ambulatory and most had no difficulty voiding. However, 7% of patients eventually required catheterization, including one patient who developed a leak and subsequent wound infection (Rattan et al, 2006).

Percutaneous techniques have been championed, especially in patients without serviceable urethral access, such as patients who have undergone previous bladder neck reconstruction or closure. This method generally involves the creation and dilation of a suprapubic tract after the bladder is distended. An Amplatz sheath is used in the vast majority of reported techniques, although concern regarding the inadvertent loss of access has compelled some to use a Hasson trocar instead (Ikari et al, 1993; Agrawal et al, 1999; Franzoni and Decter, 1999; Wollin et al, 1999; Segarra et al, 2002; Demirel et al, 2006; Aron et al, 2007; Hubscher and Costa, 2011).

A combination of ultrasonic and pneumatic energy is used to fragment the stone; small fragments may be suctioned whereas larger fragments are removed using stone forceps. In addition, an Ellik evacuator or similar device can be used to remove small fragments (Loeb et al, 2012). Placing the stones in an entrapment sac can reduce the risk of collateral damage, and this has been shown to reduce operative times (Tan et al, 2014). Suprapubic or transurethral catheter drainage is required for 1 to 5 days (Ikari et al, 1993; Franzoni and Decter, 1999; Wollin et al, 1999; Demirel et al, 2006; Aron et al, 2007).

Average operative times for percutaneous cystolithotomy range from 20 to 86 minutes (Wollin et al, 1999; Demirel et al, 2006; Aron et al, 2007), with successful eradication of stone in 89% to 100% of patients after a single procedure. Complications, including urine leak and persistent hematuria, are rare, occurring in approximately 1% of patients (Ikari et al, 1993; Franzoni and Decter, 1999; Wollin et al, 1999; Demirel et al, 2006).

Proponents of the percutaneous approach to cystolitholapaxy cite its safety and expedience, as well as the elimination of potential traumatic risk to the urethra from repeated instrument passage (Ikari et al, 1993; Wollin et al, 1999). For patients requiring surgical management for prostatic hyperplasia, transurethral resection of the prostate can be safely performed after percutaneous cystolithotomy (Aron et al, 2007).

Transurethral Cystolitholapaxy and Lithotripsy

The transurethral approach for bladder stone treatment is attractive because it allows the use of a natural orifice for access. A lithotrite may be used but this has fallen into disfavor owing to the high incidence of mucosal injury and bladder perforation as well as the inability to address large calculi and a high rate of stone recurrence (Barnes et al, 1963; Smith and O'Flynn, 1977; Nseyo et al, 1987; Bhatia and Biyani, 1994; Teichman et al, 1997; Schwartz and Stoller, 2000; Lipke et al, 2004; Singh and Kaur, 2011). Modern series report the use of the holmium laser, electrohydraulic lithotripter, and lithoclast technology, all with success in both adults and children (Bülow and Frohmüller, 1981; Teichman et al, 1997; Sathaye, 2003; Lipke et al, 2004; Okeke et al, 2004; Isen et al, 2008). However, in addition to the need for multiple probes, electrohydraulic energy is associated with a higher incidence of complications, including mucosal injury and hematuria (Teichman et al, 1997; Lipke et al, 2004). One earlier series reported a 1.6% incidence of bladder perforation with electrohydraulic lithotripsy, although this has not been reported in modern series (Bülow and Frohmüller, 1981).

Holmium laser lithotripsy has become the modality of choice, owing to its ability to treat large calculi while incurring a minimum of collateral damage. Most patients undergoing laser lithotripsy will be rendered stone free in one procedure with no major complications (Teichman et al, 1997; Lipke et al, 2004). Some favor the use of a side-firing laser, owing to the increased stability and maneuverability of the fiber as well as the shorter operative times (Teichman et al, 1997).

To prevent potential traumatic injury to the urethra from the repeated passage of instruments, one group advocates the use of a transurethral Amplatz sheath after gentle urethral dilation (Okeke et al, 2004). Should a sheath not be used, others advocate adequate urethral lubrication and preoperative meatotomy to reduce the incidence of postoperative stricture disease, although the long-term success of this strategy has not been reported (Sathaye, 2003). Concomitant transurethral resection of the prostate can be performed if necessary, and two surgeons may perform it concurrently (Zhao et al, 2013), although caution is advised owing to associated complication rates as high as 21% (Nseyo et al, 1987; Aron et al, 2007).

Shock Wave Lithotripsy

Extracorporeal shock wave lithotripsy has been successfully used for the treatment of bladder calculi. The patient is placed in a prone position to eliminate obfuscation by the pelvis and sacral spine on fluoroscopy. A Foley catheter is introduced to allow for filling and

drainage of the bladder, the latter of which provides for immobility of the stone during fragmentation, although this method is not used by all authors (Bhatia and Biyani, 1994). Cystoscopic evacuation of stone fragments is necessary for larger calculi (Bosco and Nieh, 1991; Bhatia and Biyani, 1994). Per session, 1000 to 4800 shocks are generally required to produce adequate fragmentation, and re-treatment is necessary in 10% to 25% of patients (Bosco and Nieh, 1991; Bhatia and Biyani, 1994; Millán-Rodríguez et al, 2005). Shock wave lithotripsy results in success in 93% to 100% of patients (Bosco and Nieh, 1991; Millán-Rodríguez et al, 2005).

Treatment of Stones in Augmented Bladders and Urinary Diversions

The treatment of calculi in augmented bladders and urinary diversion presents a unique challenge in that **intra-abdominal spillage of urine and irrigation can lead to peritonitis** (Palmer et al, 1993; Kronner et al, 1998; Khai-Linh and Segura, 2006). However, treatment principles remain largely unchanged from the treatment of calculi in intact bladders.

Calculi within conduit diversions are perhaps the most simple to manage, because the majority of calculi will pass spontaneously. For those calculi that do not readily pass, looposcopy with lithotripsy and stone extraction are easily performed (Shapiro et al, 1975; Middleton and Hendren, 1976; Brenner and Johnson, 1985; Ginsberg et al, 1991; L'Esperance et al, 2004). However, if stomal stenosis is diagnosed at the time of presentation, stoma revision is advised (L'Esperance et al, 2004).

Orthotopic diversions and augmented bladders may be safely treated through a transurethral approach (Kronner et al, 1998; DeFoor et al, 2004; L'Esperance et al, 2004). In patients who have undergone bladder neck reconstruction or anti-incontinence procedures, great care must be exercised to prevent disruption of the continence mechanism (Woodhouse and Robertson, 2004). The use of instrumentation up to 21 Fr with and without dilation in these instances has been reported, with no ill effects on continence (Palmer et al, 1993). **Endoscopic management through a Mitrofanoff catheterizable conduit is not advised**, because disruption of the continence mechanism can occur (DeFoor et al, 2004; L'Esperance et al, 2004). Visualization of stone fragments embedded in redundant folds of the augmented bladder may render complete eradication of stone through a transurethral approach difficult (Woodhouse and Robertson, 2004).

Success with percutaneous access to augmented bladders has been reported, although the risk of extravasation of irrigant material can occur if the bladder is not adherent to the abdominal wall. Inadvertent bowel injury and bladder perforation might occur, although the incidence is rare (Palmer et al, 1993; Docimo et al, 1998; Kaefer et al, 1998; Woodhouse and Lennon, 2001; Cain et al, 2002; Woodhouse and Robertson, 2004). In skilled hands, the **percutaneous approach can prove as efficacious as open cystolithotomy** (Docimo et al, 1998). Open cystolithotomy is often the preferred approach for large stone burdens or multiple calculi (Blyth et al, 1992; Palmer et al, 1993; Kaefer et al, 1998; Kronner et al, 1998; Woodhouse and Lennon, 2001; DeFoor et al, 2004; Woodhouse and Robertson, 2004).

The management of pouch calculi depends largely on the pouch type. **Trans-stomal endoscopic management of Indiana and Penn pouch stones is not recommended** owing to concerns regarding injury to the catheterizable limb or disruption of the continence mechanism (Patel and Bellman, 1995; L'Esperance et al, 2004; Lam et al, 2007). In such cases, percutaneous access is advocated (Arai et al, 1993; Hollensbe et al, 1993; Patel and Bellman, 1995; Beiko and Razvi, 2002; L'Esperance et al, 2004). However, the larger caliber and intussuscepted nipple of the Kock pouch allows for safe trans-stomal endoscopic access (Ginsberg et al, 1991; Cohen and Strem, 1994; Patel and Bellman, 1995; Woodhouse and Lennon, 2001). Extracorporeal shock wave lithotripsy has been attempted in a limited number of patients with good initial success (Boyd et al, 1988; Cohen and Strem, 1994).

One novel approach to the percutaneous management of pouch calculi consists of the introduction of a flexible cystoscope through the catheterizable stoma, followed by distention of the pouch. Percutaneous access is obtained under direct vision, and a laparoscopic entrapment sac is passed through the percutaneous tract. The stones are then loaded into the sac and the sac is then partially extruded through the access tract. An Amplatz sheath is introduced into the sac, and ultrasonic lithotripsy is performed to reduce the stones, allowing for extraction through the percutaneous site (Lam et al, 2007).

KEY POINTS: PRESENTATION AND MANAGEMENT

- Hematuria is the most common sign of bladder stones.
- Percutaneous cystolithotomy is highly successful in clearing bladder stones and might be less traumatic than transurethral approaches.

Bladder Calculi and Bladder Cancer

Bladder calculi may be associated with urothelial malignancy, certainly as a byproduct of malignancy in terms of encrustation of bladder tumor or necrotic areas of tissue after transurethral resection of bladder tumor (Smith and O'Flynn, 1975). In addition, some authors suggest that the presence of bladder stones may also promote malignant change through chronic irritation of the bladder mucosa, similar to the link previously noted between mucosal irritation and inflammation from long-term indwelling catheters and squamous cell bladder cancer (Groah et al, 2002; Papatsoris et al, 2006; Chung et al, 2013). However, of the few focused studies examining this relationship, in none were the researchers able to find a causal link between bladder stones and subsequent malignancy (La Vecchia et al, 1991; Jhamb et al, 2007).

PROSTATIC CALCULI

Prostatic calculi are overwhelmingly common, with 99% of asymptomatic adult men noted to have some degree of prostatic calcification at the time of autopsy, regardless of age (Søndergaard et al, 1987). Although small areas of microcalcification are generally noted during the second and third decades of life, a sharp increase in the size and overall calculus load occurs during the fifth decade of life, which is a trend that appears to continue with further aging (Klimas et al, 1985; Søndergaard et al, 1987; Bock et al, 1989; Geramoutsos et al, 2004). Prostate-specific antigen levels are unaffected by the presence of prostatic calculi (Lee et al, 2003).

Pathogenesis and Associated Anatomic Data

Prostatic calculi are believed to arise as a result of inspissation of prostatic secretions within the prostatic ducts. Subsequently, concentric layers of stone material, generally composed of calcium phosphate and calcium carbonate, are deposited on this inspissated core, resulting in gradual growth of the calculus (Sutor and Wooley, 1974; Torres et al, 1979; Kamai et al, 1999). These calculi typically remain asymptomatic throughout an individual's lifetime; however, rare cases of exceptionally large calculi causing urinary tract obstruction have been reported (Kamai et al, 1999; Bedir et al, 2005).

The majority of calculi, up to 93%, are found in the posterior and posterolateral zones of the prostate, along the course of large prostatic ducts (Young, 1934; Huggins and Bear, 1944; Fox, 1963; Hassler, 1968; Søndergaard et al, 1987). The second most common area of incidence appears to be centrally located within the anterior aspect of the prostate, found in approximately 23% of patients (Hassler, 1968; Søndergaard et al, 1987). Although scattered microcalcifications are noted within the central zone, the presence of large calculi abutting the urethra is rare, perhaps explaining the infrequency of associated obstructive urinary symptomatology

(Søndergaard et al, 1987; Kamai et al, 1999; Bedir et al, 2005). In the elderly, prostatic calculi are more commonly encountered in hyperplastic prostates with areas of nodularity; however, anatomic studies fail to show a correlation between areas of nodularity and areas of stone formation (Søndergaard et al, 1987). Prostatic calcification may occur as a rare complication of external-beam irradiation for prostate cancer (Jones et al, 1979).

Implications for Chronic Pelvic Pain Syndrome, Prostatitis, and Prostate Cancer

Given the high incidence of chronic pelvic pain in the male population (McNaughton Collins et al, 1998, 2002; Roberts et al, 1998; Benway and Moon, 2008), interest has been focused on evaluating the potential role of prostatic calculi in the natural history of chronic pelvic pain syndromes. It is estimated that 25% to 47% of men with chronic pelvic pain syndrome harbor significant areas of calcification within the prostate (Evans et al, 2007; Shokses et al, 2007), although the significance of these calculi remains unclear.

One study of males between the ages of 21 and 50 showed that patients with at least one symptom of prostatitis are 3.2 times more likely to harbor large, coarse prostatic calculi than asymptomatic age-matched cohorts, whereas diffuse areas of microcalcification do not appear to be correlated with prostatitis symptoms. Moreover, the authors noted that it is the size, and not the number of stones, that appears to correlate with the risk of pelvic pain syndromes (Geramoutsos et al, 2004).

Another study found that the presence of calculi does not correlate with the severity of prostatitis symptoms on validated questionnaires; however, the duration of reported symptoms is positively correlated with the presence of prostatic stones. Interestingly, patients with prostatic stones were less likely to demonstrate pelvic floor tenderness on examination than those patients whose imaging did not demonstrate significant prostatic calcification. In addition, patients with prostatic calculi were more likely to exhibit positive localized cultures for pathogens such as *Escherichia coli*, enterococci, *Klebsiella* species, and gram-positive pathogens, as well as higher white blood cell counts in expressed prostatic secretions (Shokses et al, 2007). However, other investigators have found no concrete association between prostatic inflammation and infection and the presence of calculi (Hassler, 1968; Søndergaard et al, 1987).

Although some reports have proposed an association between inflammation of the prostate and an increased risk of prostate cancer (Roberts et al, 2004; Sutcliffe and Platz, 2007, 2008), the lack of reliable association between prostatic calculi and inflammation casts doubt on the role of prostatic calculi in the pathogenesis of prostate cancer. Indeed a focused pathologic evaluation of patients with prostate cancer showed no association between areas of calcification and the location of adenocarcinoma (Muezzinoglu and Gurbuz, 2001).

Evaluation and Management

Because most prostatic calculi are asymptomatic, few patients will ever require specific evaluation for intraprostatic stone disease. However, imaging tests performed for other indications may show the presence of prostatic calcification. On plain film, prostatic calculi are noted in up to 14% of patients (Fox, 1963). Because computed tomography and magnetic resonance imaging are not advocated for the evaluation of patients with benign prostatic disease (Scheckowitz and Resnick, 1995), reports on the incidence of prostatic calculi with cross-sectional imaging have not been reliably documented. Transrectal ultrasonography is highly sensitive for the detection of large prostatic calculi, although it does not appear to resolve areas of diffuse calcification accurately, as evidenced by the more than twofold increase in the discovery of calcifications on pathologic sectioning (Søndergaard et al, 1987; Shokses et al, 2007).

For rare patients who experience significant morbidity from prostatic calculi, removal of the affected tissue through open

prostatolithotomy, transurethral resection, or fragmentation with holmium laser lithotripsy should prove curative (Kamai et al, 1999; Bedir et al, 2005; Shah et al, 2007; Goyal et al, 2013).

URETHRAL CALCULI

Urethral calculi are among the least common manifestations of lower urinary tract lithiasis, representing only 0.3% of all urinary stone disease in an endemic region (Aegukkatajit, 1999). Urethral calculi are exceedingly uncommon throughout industrialized Western societies but are more commonly encountered in underdeveloped nations, as well as in endemic regions throughout Asia and the Middle East (Amin, 1973; Koga et al, 1990; Seltzer et al, 1993; Aegukkatajit, 1999; Menon and Martin, 2002; Verit et al, 2006).

Urethral calculi present with a bimodal age distribution, with peak incidences in early childhood as well as in the fourth decade of life (Kamal et al, 2004; Verit et al, 2006). Increased urinary peak flow rates may exert a protective effect in the second and third decades of life by allowing for increased clearance of calculi that migrate into the urethra, which may in part account for the relative paucity of urethral stone disease noted in this demographic group (Jørgensen and Jensen, 1996; Kamal et al, 2004; Verit et al, 2006).

Pathogenesis and Composition

Urethral calculi may result from migration from the bladder or upper tracts or may arise de novo, generally in association with an anatomic abnormality such as a stricture or diverticulum or from condensation on a foreign body. They occur very rarely in females, owing to the comparatively shorter urethral length (Menon et al, 1998; Menon and Martin, 2002; Kamal et al, 2004; Verit et al, 2006; Rivilla et al, 2008).

Migratory Calculi

Migratory calculi account for a large proportion of urethral calculi in children and adults living in underdeveloped nations, where cereal-based diets predominate (Menon and Martin, 2002; Verit et al, 2006). A lower urinary tract pathologic process, such as benign prostatic hyperplasia, urethral stricture, or meatal stenosis, is often present and may serve as a predisposing factor that inhibits the ability to clear migratory calculi (Hegele et al, 2002; Kamal et al, 2004; Verit et al, 2006). Patients may also have a history of instrumentation or self-mutilation, which may contribute to urethral anomalies such as strictures (Subbarao et al, 1998).

Although the bladder was long believed to be the primary source of migratory urethral calculi (Shanmugam et al, 2000), recent evidence is challenging that supposition. Calcium oxalate is the predominant component in 86% to 100% of modern migratory urethral calculi, a component associated primarily with upper tract calculi and found rarely in native bladder calculi, where struvite and uric acid components predominate (Douenias et al, 1991; Menon et al, 1998; Kamal et al, 2004; Verit et al, 2006). Furthermore, one study showed that only 2% of patients with migratory urethral calculi had associated bladder stones, whereas 18% were found to have concurrent upper tract calculus disease (Kamal et al, 2004). In addition, in endemic areas where cereal-based diets have been abandoned in favor of more protein-rich foods, there has been a precipitous drop in the incidence of bladder calculi yet little decrease in that of urethral calculi (Aegukkatajit, 1999; Verit et al, 2006) or upper tract stone disease (Kamal et al, 2004).

Primary Urethral Calculi

Calculi that arise de novo in the urethra do so primarily through condensation of stone material on urethral foreign bodies or from stasis of urine in urethral diverticula. Struvite stones predominate, although calcium phosphate and uric acid calculi have also been reported (Singh and Neogi, 2006). Concomitant urinary

tract infection with *E. coli*, *Proteus*, or enterococci is often diagnosed at the time of presentation (Subbarao et al, 1998; Gokce et al, 2004; Gallo et al, 2007; Rivilla et al, 2008; Susco et al, 2008).

When incorporating hair-bearing grafts, urethroplasty and hypospadias repair can lead to urethral stone formation. Despite attempts at thorough epilation of the graft, hair-bearing follicles may persist, leading to symptomatic hairball formation in 3% to 8% of patients undergoing the procedure (Rogers et al, 1992; Singh and Hemal, 2001). Stone encrustation of the hairball may occur, leading to symptomatic urethral calculi that remain adherent to the graft (Singh and Hemal, 2001; Walker and Hamilton, 2001; Rodriguez-Villalba et al, 2003; Hayashi et al, 2007). In addition, exposed suture material from urethral reconstruction may serve as a nidus for stone formation (Frydenberg and Love, 1988).

For patients afflicted with maladies of the prostate, including benign prostatic hyperplasia and prostate cancer, minimally invasive alternatives to simple and radical prostatectomy are becoming more commonplace. However, despite the success of these techniques, unanticipated outcomes of these techniques may lead to urethral lithiasis. For patients who have undergone transurethral resection or ablation of the prostate for benign disease, devitalized and necrotic residual tissue, along with associated inflammation, may serve as a nidus for stone formation within the prostatic urethra (Gawande, 1986; Aus et al, 1997); stone composition in these rare cases often consists of brushite, as well as apatite and calcium oxalate (Magura et al, 1980; Gawande, 1986). In addition, proteinaceous secretions from the residual tissue may also serve as a nidus for stone accumulation; in such instances, apatite and calcium phosphate may comprise a larger proportion of stone material (Sutor and Wooley, 1974; Gawande, 1986).

Urethral calculi are also a rare long-term complication of patients undergoing brachytherapy and cryoablation of the prostate for carcinoma. Radioactive seeds left in situ after administration of brachytherapy may be prone to migration. Seeds that migrate into the urethra can serve as a nidus for calcification. Often these patients present with a primary complaint of intermittent gross hematuria instead of the obstructive symptoms more commonly encountered in other forms of urethral lithiasis (Steinmetz and Barrett, 2006). Urethral calculi are also reported as rare complications of prostate cryotherapy for carcinoma, again with necrotic residual tissue serving as a nidus for stone formation. Previous treatment with external-beam irradiation and inadequate urethral warming appear to contribute to an increased risk of postoperative urethral lithiasis (Aus et al, 1997).

Finally, urethral lithiasis may arise as a secondary complication from self-mutilation. For instance, one report describes encrustation of two safety pins that had been inserted by a mentally handicapped patient. The stone was discovered after an indolent course with only mild lower urinary tract symptomatology (Gokce et al, 2004).

Calculi within Urethral Diverticula

Calculi found in association with a urethral diverticulum may either represent a primary calculus resulting from stasis of urine or they may represent collection of migratory stone material (Dorairajan, 1963; Subbarao et al, 1998; Shanmugam et al, 2000; Walker and Hamilton, 2001). Stones will form in 1% to 10% of all urethral diverticula (Beatrice and Strebel, 2008); and with only one documented exception in the literature, a urethral diverticulum is present in nearly all reported cases of urethral calculi in females (Martínez-Maestre et al, 2000; Gallo et al, 2007; Beatrice and Strebel, 2008; Rivilla et al, 2008; Susco et al, 2008). Diverticula may arise from congenital malformation or from traumatic or iatrogenic injury to the urethra, including straddle injuries, vaginal delivery, periurethral gland abscess, pelvic fracture, endoscopic and open surgical misadventure, and long-term urethral catheterization (Mohan et al, 1980; Parker et al, 2007; Beatrice and Strebel, 2008; Lin et al, 2008). However, antecedent urethral injury is absent in 50% to 90% of reported cases of male urethral diverticula (Marya et al, 1977; Bazeed et al, 1981). Stone composition of these calculi

has not been reliably reported in the literature, although diverticular calculi are often associated with urinary tract infection (Subbarao et al, 1998; Gallo et al, 2007; Susco et al, 2008).

Presentation and Evaluation

The presentation of urethral calculus largely depends on pathogenesis and location of the stone within the urethra. Patients with migratory calculi often present with acute lower urinary tract symptoms from sudden impaction of the stone, including stranguria, urinary retention, gross hematuria, and dysuria, whereas those with de novo urethral calculi and those residing in diverticula often present with more insidious symptoms. Urinary tract infection is frequently diagnosed at the time of presentation (Hassan and Mahammed, 1993; Subbarao et al, 1998; Shanmugam et al, 2000; Kamal et al, 2004). In women, urethral calculi can be associated with chronic pelvic pain (Thomas and Crew, 2012).

In one large contemporary series, acute urinary retention was the presenting complaint in 78% of all patients with urethral calculi, whereas an additional 22% reported decrease of the urinary stream with dribbling of urine (Kamal et al, 2004). Older reports vary widely, however, in terms of presentation, with urinary retention rates as low as 0% and as high as 89% (Amin, 1973; Selli et al, 1984; Sharfi, 1991).

Migratory urethral calculi are typically solitary, although multiple calculi have been reported as urethral steinstrasse after shock wave lithotripsy and also in one child with a proximal urethral stricture resulting from self-mutilation (Biyani et al, 1993; Subbarao et al, 1998; Atikeler et al, 2005; Verit et al, 2006). A total of 32% to 88% reside in the posterior urethra, whereas 8% to 58% are located in the bulbous and penile urethra and 4% to 11% are found at the fossa navicularis (Shanmugam et al, 2000; Kamal et al, 2004).

Calculi within urethral diverticula may be either singular or multiple. Their natural history is often insidious, with minimal obstructive symptoms. Rather, a protracted course of increasing lower abdominal, pelvic, and perineal discomfort, as well as hematuria, dysuria, and dyspareunia, is often the norm (Subbarao et al, 1998; Koh et al, 1999; Martínez-Maestre et al, 2000; Gallo et al, 2007; Beatrice and Strebel, 2008; Susco et al, 2008). In females, urinary frequency and stress urinary continence also have been reported (Susco et al, 2008).

Patients do not often seek treatment immediately, with delays ranging from several months to up to 10 years (Koh et al, 1999; Gallo et al, 2007; Beatrice and Strebel, 2008; Rivilla et al, 2008; Susco et al, 2008). In instances of prolonged delays in diagnosis, urethrocuteaneous or urethrorectal fistulae may develop and may serve as the presenting complaint, especially in patients unable to report lower urinary tract discomfort, such as infants and patients with spinal cord injuries (Kaplan et al, 2006; Shamsa et al, 2008).

In most cases of penile and female urethral calculi, the stone is readily palpable on examination, often recognized as a hard mass along the expected course of the male urethra or as a firm mass in the anterior vaginal wall (Subbarao et al, 1998; Martínez-Maestre et al, 2000; Gokce et al, 2004; Kaplan et al, 2006; Gallo et al, 2007; Beatrice and Strebel, 2008; Susco et al, 2008). Prostatic calculi are less commonly palpable and often require imaging or cystoscopic visualization to confirm the diagnosis (Gawande, 1986; Aus et al, 1997; Steinmetz and Barrett, 2006).

Despite early reports indicating that 60% of urethral calculi were radiolucent, in the modern era 98% to 100% of urethral calculi are radiopaque and can be visualized on plain radiographs (Kamal et al, 2004; Verit et al, 2006). In addition, prostatic calculi are easily visualized on transrectal ultrasonography, as evidenced by significant shadowing around an area of increased signal density (Aus et al, 1997). However, given the potential for associated anatomic abnormality, many authors now advocate the use of urethrography or cross-sectional imaging to aid in diagnosis (Koh et al, 1999; Singh and Hemal, 2001; Hayashi et al, 2007; Rivilla et al, 2008; Susco et al, 2008).

Treatment

Treatment of urethral calculi is largely determined by their location within the urethra, as well as by the presence of an associated anatomic pathologic process such as a diverticulum. Stones located in the posterior urethra may be pushed back into the bladder for subsequent fragmentation with electrohydraulic or laser lithotripsy, a procedure that includes a success rate of 66% to 86% (Aus et al, 1997; Kamal et al, 2004; Verit et al, 2006). If subsequent fragmentation in the bladder is unsuccessful, open cystolithotomy may be required (Kamal et al, 2004). Shock wave lithotripsy after pushback into the bladder has been reported, although success rates were only reported at 60% (El-Sharif and Prasad, 1995).

For stones in the anterior urethra, retrograde relocation to the bladder is rarely feasible and should therefore not be attempted. However, extraction of the stone by “milking” may be successful, provided the stone is smooth; the risk of urethral injury related to this method of extraction is unknown, and thus caution should be exercised (Rodriguez Martinez et al, 2000; Kamal et al, 2004; Maheshwari and Shah, 2005). In addition, milking of the calculus is not advocated if the stone is large or irregular or if it has a spiked surface (Kamal et al, 2004). Some authors have noted success with spontaneous expulsion of small distal stones after the intraurethral administration of lidocaine jelly (El-Sharif and El-Hafi, 1991; Kamal et al, 2004). Success with simple cystoscopic extraction has also been reported (Atikeler et al, 2005).

For calculi not amenable to simple manipulation, urethrotomy with stone extraction has long been the norm and is still advocated when concurrent urethroplasty or urethrocuteaneous fistula repair is required (Singh and Hemal, 2001; Gokce et al, 2004). Reports suggest, however, that *in situ* lithotripsy of urethral calculi may be feasible, with reported success rates of up to 80% (Kamal et al, 2004). Electrohydraulic and Swiss lithoclast fragmentation has been reported, although concerns exist regarding the potential for collateral damage to the surrounding urethral tissue (El-Sharif and El-Hafi, 1991; Koh et al, 1999; Kamal et al, 2004; Verit et al, 2006; Hayashi et al, 2007). Holmium laser lithotripsy has therefore been advocated, citing excellent efficacy with minimal trauma to the surrounding urethral tissue (Walker and Hamilton, 2001; Maheshwari and Shah, 2005).

Stones within diverticula may be addressed with incision of the diverticulum and stone extraction, although success with *in situ* lithotripsy has been reported in a female patient (Subbarao et al, 1998; Singh and Neogi, 2006; Susco et al, 2008). Diverticulectomy and urethral repair may be performed concurrently or in a staged fashion (Subbarao et al, 1998; Martínez-Maestre et al, 2000; Karanth et al, 2003; Singh and Neogi, 2006).

PREPUTIAL CALCULI

Preputial calculi are relatively uncommon manifestations of lower tract calculus disease, with only a handful of reported cases in the literature during the past 2 centuries. Preputial calculi may occur at any age but are far more common among adults and the elderly (Sharma and Bapna, 1977).

Virtually all cases of preputial calculi are associated with severe phimosis in uncircumcised males. Additional risk factors include poor hygiene and low socioeconomic status (Ellis et al, 1986).

Preputial calculi are postulated to arise from one of three possible mechanisms, including inspissated smegma, stasis with precipitation of urinary salts, or a combination of the two, typically with a nidus of smegma acting as a condensation nucleus for the precipitation of urinary salts (Winsbury-White, 1954; Ellis et al,

1986; Mohapatra and Kumar, 1989). In addition, smegma itself may act as a direct local irritant leading to inflammation and scarring of the prepuce, which can cause further obstruction and urinary stasis (Parkash et al, 1973; Mohapatra and Kumar, 1989) and in some cases might create phimosis so severe that the prepuce may serve as an expansile urinary reservoir that collects large amounts of voided urine (Williamson, 1932). Other less common avenues of pathogenesis include the presence of a foreign body, such as suture material (Ellis et al, 1986), as well as trapping of voided bladder calculi in patients with severe phimosis (Williamson, 1932; Nagata et al, 1999).

In nearly all reported cases of preputial calculi, **progressive difficulty with voiding is the most common presenting complaint**. Other symptoms may include dysuria, gross hematuria, foul-smelling discharge, ballooning of the prepuce with voiding, and palpable calculi within the preputial sac (Williamson, 1932; Shahi and Ram, 1962; Sharma and Bapna, 1977; Ellis et al, 1986; Mohapatra and Kumar, 1989; Nagata et al, 1999). In rare cases, presentation may be delayed until urinary retention develops (Shahi and Ram, 1962).

Evaluation includes careful history, noting the duration and nature of symptoms, as well as history of calculus disease. On physical examination, tight phimosis is often encountered along with inflammation of the prepuce (Williamson, 1932; Shahi and Ram, 1962; Sharma and Bapna, 1977). The stones are often palpable on examination and may be freely mobile within the preputial sac (Williamson, 1932). Bilateral inguinal lymphadenopathy, if present, should raise the suspicion of concurrent penile carcinoma (Mohapatra and Kumar, 1989). Imaging with plain radiography may help to confirm the diagnosis of preputial calculi (Mohapatra and Kumar, 1989; Nagata et al, 1999).

Treatment involves removal of the calculi as well as the primary cause of urinary obstruction and stasis, generally by circumcision or a dorsal slit procedure (Williamson, 1932; Shahi and Ram, 1962; Sharma and Bapna, 1977; Mohapatra and Kumar, 1989; Nagata et al, 1999). All foreign objects, including suture material, should be removed in their entirety (Ellis et al, 1986). The excised preputial tissue should be sent for histopathologic evaluation to rule out carcinoma. In addition, if an underlying ulceration of the glans is noted, a biopsy of the lesion should also be submitted for pathologic evaluation (Sharma and Bapna, 1977; Mohapatra and Kumar, 1989).

Opening of the preputial sac generally shows multiple smooth, rounded calculi, which are brittle on examination (Williamson, 1932; Shahi and Ram, 1962). Stone composition varies in published reports but stones are most commonly composed of ammonium magnesium phosphate; however, other materials, including urate, calcium phosphate, and calcium oxalate, may be encountered as well (Sharma and Bapna, 1977; Ellis et al, 1986; Mohapatra and Kumar, 1989; Nagata et al, 1999). Culture may show the growth of various pathogens, including enterococci and *E. coli*, the latter of which may be carcinogenic (Hawksworth and Hill, 1971; Ellis et al, 1986; Mohapatra and Kumar, 1989). All symptoms typically completely resolve after circumcision and calculus removal.

Renal Cysts

Papillary Adenoma of the Kidney

Metanephric Adenoma

Oncocytoma

Angiomyolipoma

Mixed Mesenchymal and Epithelial Tumors

Cystic Nephroma

Mixed Epithelial and Stromal Tumors

Leiomyoma

Other Benign Renal Tumors

Benign renal neoplasms constitute a rather large and heterogeneous group of renal lesions that can be found in the kidney. These include the simple renal cyst, selected complex renal cysts, cortical and metanephric adenomas, angiomyolipoma, oncocytoma, the rarer cystic nephroma, mixed epithelial-stromal tumor, and leiomyoma, as well as other, even more esoteric tumor types. Management approaches to these lesions can vary widely, from no management for the simple renal cyst to selective embolization for larger angiomyolipomas and surgical extirpation for solid renal masses when the differential diagnosis includes renal cell carcinoma (RCC). With the increased use of cross-sectional abdominal imaging for renal-specific as well as other nonspecific complaints, it is expected that the identification of both benign and malignant renal tumors will continue to increase in the coming years (Patard, 2009). Moreover, with the increased use of and refinements in renal mass biopsy, the management of both benign and malignant renal neoplasms is still evolving in such a way that the indications for intervention, and the type of intervention, may change significantly in the coming years (Lane et al, 2008a; Campbell et al, 2009). Now, with advanced multidimensional imaging techniques as well as minimally invasive, nephron-sparing surgical approaches, percutaneous ablative approaches, and the concept of active surveillance in the armamentarium of the practicing urologist, management of all renal lesions, including those that are presumptively benign, continues to evolve (Raj et al, 2007; Benway and Bhayani, 2009; Murphy et al, 2009).

At present, however, the urologist is left primarily with imaging studies such as ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) to assess whether a renal lesion is benign or malignant before therapeutic decisions are made. And unless the mass has clear radiographic features that suggest a benign cause, such as clear evidence of fat seen with most angiomyolipomas or the smooth walls and lack of enhancement of a simple or minimally complex cyst, the vast majority of benign renal lesions are diagnosed only after definitive therapy such as surgical intervention has been implemented. Several clinical features have been linked to an increased likelihood of a renal mass having a benign cause, including smaller size of mass and female sex and older age of patient, but none of these factors can be relied on to avoid intervention if a specific pretherapy diagnosis cannot be made (Kutikov et al, 2006; Snyder et al, 2006; Glassman et al, 2007; Lane et al, 2007; Beisland et al, 2009; Murphy et al, 2009).

In this chapter the most common benign renal neoplasms that occur in the kidney are identified. The discussion is then focused on the etiology and natural history, clinical presentation, histology and molecular biology, imaging characteristics, and treatment options, when treatment is indicated.

RENAL CYSTS

In much the same way as the molecular biology of RCC was elucidated through the study of familial genetic syndromes such as von Hippel-Lindau disease, the molecular basis for cyst formation has been further elucidated through the genetic analysis of familial renal cystic syndromes, such as autosomal dominant polycystic kidney disease (ADPKD) and autosomal recessive polycystic kidney disease (ARPKD). Through these studies researchers have identified that loss of specific genes, such as *PKD1* (encodes for polycystin-1 protein) or *PKD2* (encodes for polycystin-2 protein), leads to cyst formation in patients with ADPKD. Polycystin-1 and polycystin-2 form a complex that represents a critical ion channel in the kidney, the loss of which results in cyst formation through the loss of intracellular calcium dysregulation (Pei, 2003; Weimbs, 2007; Ibraghimov-Beskrovnaya and Bukanov, 2008). More recently, defects in primary cilia—nonmotile organelles present on the surface of renal tubular epithelial cells—have been implicated in renal cystic diseases, and much research is currently being conducted to further elucidate this link (Lina and Satlinb, 2004). Similarly, mutations in the *PKHD1* (polycystic kidney and hepatic disease 1) gene, which encodes the fibrocystin/polyductin protein (normally interacts with polycystin-2), were found to be the cause of ARPKD (Onuchic et al, 2002). Whether these genetic changes are common to sporadic forming “benign” renal cystic disease remains to be proven, but many of the phenotypic and genetic changes noted in the kidneys of patients with familial cystic disease syndromes have been identified in sporadic cystic disease (Qian et al, 1996; Pei, 2001).

Perhaps the best description of the natural history of sporadic renal cysts can be found in the recently updated study by Terada and associates (2008). In this study of 61 patients with simple renal cysts and a mean of 10 years of follow-up, the authors noted that the cysts increased in both size and number over time. The average increase in size of the cysts was 1.9 mm/yr, but the authors

also noted that the rate of size increase decreased with age. It is interesting to note that two cysts developed renal neoplasms during the course of the study, and no differences were noted in the clinical characteristics of the cysts that developed neoplasms and those that did not. Regarding the risk factors for the development of cysts, increasing age, male gender, presence of hypertension, and presence of renal insufficiency were all associated with the development of sporadic renal cysts (Terada et al, 2004). Renal cysts remain the most common benign renal lesions, representing more than 70% of asymptomatic renal masses. They can be solitary or multiple and unilateral or bilateral (Terada et al, 2002).

In addition to sporadic cystic disease of the kidney and the cysts that occur with familial syndromes such as ADPKD and ARPKD, cysts are also known to occur in association with end-stage renal disease in patients on dialysis (Bisceglia et al, 2006). There appears to be a higher incidence of RCC associated with the development of acquired renal cystic disease, much like that seen with von Hippel-Lindau disease and tuberous sclerosis, such that the pathogenesis of these cystic lesions may be quite different from

that seen with sporadic simple or minimally complex cysts (Truong et al, 2003).

Renal cystic lesions can be imaged through a variety of radiographic techniques, including ultrasonography, CT, and MRI. On ultrasonography, simple renal cysts have a smooth wall, are fluid filled with no internal echoes, and have evidence of posterior wall enhancement. Evidence of internal echoes, calcifications or nodularity in the wall, or internal septa on ultrasonography suggests a more complex cyst that might be worthy of further imaging that includes intravenous administration of a contrast agent (Quia et al, 2008; Eknayan, 2009).

The Bosniak classification for renal cystic lesions, as reviewed in Table 56-1, is the most useful and widely employed method for characterizing renal cystic lesions and for assessing the likelihood of the presence of a concomitant malignancy within the cyst (Bosniak, 1986; Israel and Bosniak, 2005; Warren and McFarlane, 2005). In general, Bosniak class I, II, and IIF cysts are likely to represent benign lesions, thus requiring either no therapy or just continued radiographic follow-up, in the case of class IIF lesions (Fig. 56-1). These recommendations are based on a number of

TABLE 56-1 Bosniak Classification of Renal Cysts

BOSNIAK CLASSIFICATION	IMAGING CHARACTERISTICS	INCIDENCE OF MALIGNANCY	THERAPY
I	Simple cyst with a hairline thin wall that does not contain septa, calcifications, or solid components. It measures water density in Hounsfield units and does not enhance with intravenous administration of a contrast agent.	1.7%	No therapy or follow-up required
II	Cyst may contain a few hairline thin septa and fine calcifications, or a short segment of slightly thickened calcification may be present in the wall or septa. Uniformly high-attenuation lesions <3 cm (so-called <i>high-density cysts</i>) are well margined and do not enhance with intravenous administration of a contrast agent.	18.5%	No therapy or follow-up required
IIF	Cysts may contain multiple hairline thin septa or minimal smooth thickening of their wall or septa. Their wall or septa may contain calcifications that may be thick and nodular, but no measurable contrast enhancement is present. These lesions are typically well margined. Totally intrarenal nonenhancing high-attenuation renal lesions ≥3 cm are also included in this category.	18.5%	Repeat imaging to assess stability of size and radiographic characteristics
III	“Indeterminate” cystic masses have thickened irregular or smooth walls or septa in which measurable contrast enhancement is present.	33%	Excision or ablation
IV	Clearly malignant cystic masses can have all the criteria of category III but also contain enhancing soft-tissue components.	92.5%	Excision or ablation

Figure 56-1. A, Computed tomography (CT) scan of a Bosniak I renal cyst. B, CT scan of a Bosniak II renal cyst. Note internal calcification. C, CT scan of a Bosniak IIF renal cyst. Several thin irregular septations are present within the cyst. (Copyright 2009, C. G. Wood.)

Figure 56-2. A, Computed tomography (CT) scan of a Bosniak III renal cyst. Thick, irregular septations are present within the cyst. series published in the literature by Bosniak and others that include both radiographic as well as pathologic follow-up (Israel and Bosniak, 2003; Warren and McFarlane, 2005; Gabr et al, 2009; O'Malley et al, 2009).

Because of the higher risk of malignancy associated with Bosniak class III and IV lesions, therapy is recommended (Fig. 56-2). The definitive therapy would be surgical excision, although ablative therapies such as cryotherapy or radiofrequency ablation of cystic masses have been reported (Raman et al, 2009) (see Chapter 57).

Although the Bosniak classification was originally devised and implemented using CT scans, it can be used with MRI as well, although caution must be exercised because MRI tends to exaggerate some findings related to cysts (Bosniak, 2012). For example, MRI can make septa appear thicker, which could make enhancement of cyst walls and septa more obvious, as a result of inferior spatial resolution and superior contrast resolution with MRI. This could make Bosniak II cysts look like IIF and IIF look like III, especially in cysts less than 2.5 cm in size. However, MRI does have an advantage in hemorrhagic lesions or other lesions that have high intensity on CT (Bosniak, 2012).

The overwhelming majority of simple or minimally complex cysts require no further follow-up or therapy once diagnosed (Eknoyan, 2009). Rarely, benign cystic lesions of the kidney can grow to such a large size that they can cause pain or other symptomatology, including hypertension (Porpiglia et al, 2009; Zerem et al, 2009). Symptoms can also occur as a consequence of hemorrhage within the cyst or spontaneous or traumatic cyst rupture (Hughes et al, 1995; Rainio et al, 2006; Ishikawa et al, 2008; Vaidyanathan et al, 2008).

A variety of therapeutic interventions have been described for benign symptomatic cystic lesions of the kidney. These include aspiration, surgical resection, cyst decortications, and sclerotherapy with a variety of different agents (Cho et al, 2008; Ham et al, 2008; Baysal and Soylu, 2009; Canguven et al, 2009; Choi et al, 2009; Porpiglia et al, 2009). Although none of these approaches seems to be better than the others described, it is noted that with aspiration and sclerotherapy there is a higher incidence of cyst recurrence and multiple treatments may be needed to satisfactorily ablate the cystic lesion. A word of caution is warranted regarding the treatment of peripelvic cysts: given their proximity to the vital structures of the kidney, including the renal vessels and collecting system, laparoscopic rather than percutaneous approaches may be associated with a higher safety margin and better efficacy (Okumura et al, 2003; Camargo et al, 2005).

KEY POINTS: RENAL CYSTS

- Renal cysts remain the most common of benign renal lesions, representing more than 70% of asymptomatic renal masses.
- The overwhelming majority of simple or minimally complex cysts require no further follow-up or therapy once diagnosed.
- The Bosniak classification for renal cystic lesions is the most useful and widely employed method for characterizing renal cystic lesions and assessing the likelihood of the presence of a concomitant malignancy within the cyst.

PAPILLARY ADENOMA OF THE KIDNEY

The designation and management of papillary adenomas remain a subject of controversy in the urologic literature. These lesions are small, solid cortical renal lesions that are thought to have a benign course (Renshaw, 2002). To be considered papillary adenomas, these lesions should histologically be 5 mm or smaller; well circumscribed; characterized by uniform basophilic or eosinophilic cells with benign-appearing nuclear and cellular features; and arranged in papillary, tubular, or tubulopapillary architecture; and they should not resemble clear cell, chromophobe, or collecting duct RCC (Grignon and Eble, 1998). The incidence of papillary adenomas increases with age (40% of patients over 70 years of age in autopsy studies) and male sex, and these tumors also have been associated with acquired renal cystic disease that results in end-stage renal failure (Xipell, 1971; Hughson et al, 1986; Reis et al, 1988; Leroy et al, 2001; Denton et al, 2002; Snyder et al, 2006; Ferda et al, 2007). The incidence of papillary adenomas in autopsy series ranges from 7% to 23%, although antemortem pathologic diagnosis of renal adenoma is much less common, in part owing to the pathologist's concern that there are no reliable histopathologic, ultrastructural, or immunohistochemical criteria to distinguish benign from malignant lesions of the kidney (Licht, 1995). In fact, in a more recent study in which immunohistochemical analyses were used to further characterize renal adenomas, it was suggested that these lesions may be linked to the development of papillary RCC and represent a biologic link and continuum as a premalignant precursor (Wang et al, 2007). In this study, researchers examined 542 nephrectomy specimens obtained over 8 years. Seven percent of these demonstrated evidence of papillary adenoma; and of these, 47% were associated with a

concomitant papillary RCC, whereas 53% were associated with other renal tumor histologies. Papillary adenomas that arose in the setting of papillary RCC tended to be multiple (61%), whereas papillary adenomas associated with other renal tumors were only one or two in number. Eighty-two percent of papillary adenomas found in the study had a similar immunohistochemistry staining profile to papillary RCC, staining positive for AMACR. In other studies, renal adenomas shared similar cytogenetic profiles to papillary RCC, such as loss of Y chromosome and trisomy of chromosomes 7 and 17, thus suggesting a biologic link between the two neoplasms, with papillary adenomas being potential precursor lesions (Kovacs et al, 1991; Kovacs, 1993; Presti et al, 1998; Brunelli et al, 2003a).

The overwhelming majority of papillary adenomas remain asymptomatic, are undetectable radiographically because of their small size (<1 cm), and require no further therapy. Size of the neoplasm has historically been used to differentiate renal adenoma from more malignant neoplasms of the kidney. Thoenes and colleagues (1986) provided a reassessment of the histologic classification of renal tumors and defined renal adenoma as a tumor with nuclear grade I and a diameter of at least 1 cm. For many years, a “3-cm rule” was pervasive in the urologic literature, dating back to the original autopsy studies by Bell (1938) in which he noted that only 1 of 38 renal cortical tumors had associated metastases whereas 70 of 106 tumors larger than 3 cm were associated with metastases.

The diagnosis of papillary adenoma remains controversial; many believe that all solid renal epithelium-derived masses are potentially malignant and therefore should undergo treatment (Renshaw, 2002).

KEY POINTS: PAPILLARY ADENOMA OF THE KIDNEY

- The diagnosis of papillary adenoma remains controversial; many believe that all solid renal epithelium-derived masses are potentially malignant and therefore should undergo treatment.
- Papillary adenomas may be linked to the development of papillary RCC and could represent a biologic link and continuum as a premalignant precursor.
- The incidence of papillary adenomas increases with age and male sex, and these tumors also have been associated with acquired renal cystic disease seen in patients on hemodialysis.

METANEPHRIC ADENOMA

In 1995, Davis and colleagues (1995) reported 50 cases of an unusual and new renal lesion with distinctive histologic features and a benign clinical course despite occasional symptomatic presentation and large tumor size. In this series, mean tumor size was 5.5 cm (up to 15 cm), and nearly half of the patients had flank pain, gross hematuria, or a palpable mass. Six additional patients had polycythemia, and hypercalcemia has also been reported in association with this tumor type, which was designated *metanephric adenoma* (Davis et al, 1995; Mahoney et al, 1997; Kuroda et al, 2003b). Metanephric adenoma was officially accepted as a primary benign renal tumor based on consensus from the Heidelberg classification (Kovacs et al, 1997). A female predominance (2:1) has been noted in several series (Davis et al, 1995; Jones et al, 1995; Snyder et al, 2006; Bastide et al, 2009). Incidental presentation is most common, and peak incidence is in the fifth decade of life (Renshaw, 2002). Polycythemia can be seen in 10% of patients and appears to be caused by the production of erythropoietin and other cytokines by the tumor (Yoshioka et al, 2007; Bastide et al, 2009). Radiographically these tumors can have peripheral or central calcifications and may be hypovascular on contrast-enhanced CT and hyperechoic on ultrasonography (Bastide et al, 2009). These tumors

Figure 56-3. Classic metanephric adenoma with small, intensely basophilic cells arranged in an acinar pattern.

tend to be solitary, hypodense or isodense, with a poorly defined margin, with less enhancement than the medulla and cortex during all contrast-enhanced CT phases (Zhu et al, 2014).

On microscopic examination these tumors consist of very small, often highly basophilic epithelial cells that form small acini and occasionally tubular or papillary structures within a predominantly acellular stroma (Fig. 56-3). Davis and colleagues (Renshaw, 2002) argued that metanephric adenoma might be histologically related to epithelial Wilms tumor because they believed that it exhibited histologic similarities to the metanephric, hamartomatous elements of nephroblastomatosis. Along these lines, it is interesting to note that many of these tumors exhibit evidence of regression in the form of scarring or calcification. In addition, Muir and colleagues (2001) have shown positive staining for the Wilms tumor protein WT1 and an immunohistochemical staining profile that suggests a histogenetic relationship to Wilms tumor. An alternative theory for the origin of metanephric adenoma was proposed by Brown and associates (1997), who found gain of chromosomes 7 and 17 by fluorescent in situ hybridization in 8 of 11 of these tumors. These findings suggest a clonal neoplastic disorder potentially related to papillary RCC, but others have argued that this series may have been contaminated by inclusion of some cases of papillary RCC, which can be difficult to differentiate from metanephric adenoma (Brunelli et al, 2003b). Szponar and colleagues (2010) performed high-resolution array comparative genomic hybridization (array CGH) on six patients with metanephric adenoma, and none showed any DNA copy number changes. Pan and Epstein (2010) also performed array CGH on nine patients, and conversely noted only four patients with normal chromosome copy numbers. Five patients had gain of chromosome 19, confirmed using fluorescence in situ hybridization (FISH). Arroyo and colleagues (2001) showed that metanephric adenomas are part of a spectrum of related tumors, bridging metanephric stromal tumors, metanephric adenofibromas, and Wilms tumor. This potential link was also reviewed by Argani (2005). Pesti and colleagues (2001) have described a putative tumor suppressor gene for metanephric adenoma at chromosome 2p13. Various immunohistochemical stains have been evaluated to help distinguish metanephric adenoma from other renal neoplasms. The Wilms tumor marker WT1 is frequently expressed in metanephric adenoma (Muir et al, 2001; Bosco et al, 2007). α -Methylacyl-CoA racemase (AMACR) is poorly expressed in metanephric adenoma but highly expressed in papillary RCC (Olgac et al, 2006), whereas S-100 protein expression is very high in metanephric adenoma, weak in Wilms tumor, and absent in papillary RCC (Azabdaftari et al, 2008). Skinnider and colleagues (2005) demonstrated the potential utility of an expression panel to help differentiate papillary RCC and metanephric adenoma using a panel of cytokeratins 7, 8, 18, and 19 and vimentin. Use of these various markers appears to have improved the diagnostic yield of percutaneous biopsy and

fine-needle aspiration (Bosco et al, 2007; Patel et al, 2009), but the index of initial suspicion needs to be high for biopsy to be considered. Recently, Choueiri and colleagues (2012) evaluated *BRAF* V600E status in 29 patients with metanephric adenoma, and noted that 90% had *BRAF* V600E mutations. Such a mutation could be potentially studied during investigation of small renal masses with percutaneous biopsies.

Only one case of metastasis has been described in association with classic metanephric adenoma into a regional lymph node, and death related to this entity has not been reported (Drut et al, 2001). However, Picken and colleagues (2001) have described a single case of malignant stromal elements associated with a metanephric neoplasm of the kidney in a 21-year-old woman who died of progressive cancer, and they have proposed that there may be a spectrum of metanephric tumors that includes rare, aggressive variants. Atypical histologic features and multifocality in childhood have also been reported (Jain et al, 2007; Kohashi et al, 2009). Given the rarity of this tumor and the lack of highly predictive clinical or radiographic criteria, metanephric adenoma remains primarily a pathologic diagnosis. If radiographic findings raise the index of suspicion, then percutaneous core biopsy with fine-needle aspiration may prove helpful in establishing a diagnosis for nephron-sparing treatment or observation, but most patients will require surgical excision because of concern for malignancy (Fig. 56-4).

KEY POINTS: METANEPHRIC ADENOMA

- Metanephric adenoma is a recently described, rare, benign mass that radiographically may be indistinguishable from RCC.
- It is typically found incidentally, has a female predominance, and has a peak incidence in the fifth decade of life.
- The diagnosis is often made after surgical excision and can be confirmed with immunohistochemical panels for cytokeratins, WT1, S-100, and AMACR and by checking for *BRAF* V600E mutations.

ONCOCYTOMA

Renal oncocytoma is the most common benign tumor that appears as an enhancing renal mass on cross-sectional imaging and is presumed to be RCC until surgical excision, representing one of the ultimate challenges in preoperative diagnosis for the urologist. It accounts for 3% to 7% of kidney tumors (Morra and Das, 1993). Oncocytoma was initially described by Zippel in 1942 (Zippel,

1942) and then became accepted as a distinct entity after a report of 13 cases in 1976 by Klein and Valensi (Klein and Valensi, 1976). Multiple additional reports since that time, including more recent genotyping studies, confirm it to be a benign histology with a distinct cell of origin and genetic abnormalities (Lieber et al, 1987; Davis et al, 1991; Licht et al, 1993; Amin et al, 1997; Perez-Ordóñez et al, 1997; Dechet et al, 1999; Chao et al, 2002; Kuroda et al, 2003a). Cases of metastatic disease have been reported, yet these are considered exceptionally rare and may represent cases of malignant degeneration or pseudometastases (Paner et al, 2005; Oxley et al, 2007).

Recent clinical studies highlight the differing incidence of oncocytoma based on age and gender. Cao and colleagues (2005) and Skolarus and colleagues (2008) showed an increasing incidence of oncocytoma in older patients with a small incidentally discovered renal mass. Two different reports highlight that younger females are nearly twice as likely as their male counterparts to have a benign tumor, which includes oncocytoma and angiomyolipoma; these findings are probably largely driven by the higher rates of angiomyolipoma in women (Cao et al, 2005; Snyder et al, 2006).

Grossly these tumors are mahogany or tan, homogeneous, and well circumscribed with a pseudocapsule and a central stellate scar in some patients (Fig. 56-5). Microscopically the cells are round or polygonal and arranged in a nested growth pattern. The cells are large, uniform, and highly eosinophilic, owing to an abundance of mitochondria (Renshaw, 2002). In up to one third of patients, hemorrhage, extension into perinephric fat, vascular invasion, cellular atypia, prominent nucleoli, and pleomorphism may be seen, yet the clinical behavior in these cases is within what is expected with a benign course (Davis et al, 1991; Amin et al, 1997; Perez-Ordóñez et al, 1997). The most common genetic abnormality is loss of heterozygosity at chromosomes 1 and/or 14 (Presti et al,

Figure 56-4. Computed tomography scan showing a metanephric adenoma in a middle-aged woman. (Copyright 2009, S. F. Matin.)

Figure 56-5. A, Bivalved renal oncocytoma demonstrating central scar. B, Oncocytoma with large eosinophilic cells arranged in distinct nests.

1996; Herbers et al, 1998; Lindgren et al, 2004; Paner et al, 2007). Other common cytogenetic findings include loss of the Y chromosome and chromosome 14q and rearrangements of 11q13 (Schwerdtle et al, 1997; Herbers et al, 1998; Chao et al, 2002; Polascik et al, 2002; Lindgren et al, 2004). The chromosomal abnormalities typically seen in RCC are not seen in renal oncocytomas, further reinforcing the concept that these tumors are genotypically distinct from RCC (Herbers et al, 1998; Minor et al, 2003). However, histologically, the greatest dilemma arises from distinguishing chromophobe and clear cell RCC with eosinophilic characteristics from oncocytoma. Hale colloidal iron staining is the classic differentiating marker for oncocytoma, but it can have nonspecific staining and be difficult to interpret (Leroy et al, 2000). Cytokeratin profiles are helpful in distinguishing these histologic findings (Skinnider et al, 2005; Adley et al, 2006). Expression of cytokeratin-7 is seen in 66% of chromophobe RCC and only 5% of oncocytomas, and parvalbumin is expressed in 100% of chromophobe RCC and 47% of oncocytomas (Leroy et al, 2000; Adley et al, 2006). Various other markers have been recently described to differentiate oncocytoma from RCC, particularly chromophobe RCC, but the clinical usefulness of most of these has not yet been fully developed. These include Pax-2, expressed in metanephric tissues and vital for renal tubule development; pattern of claudin-7 and claudin-8 expression (Osunkoya et al, 2009); tight junction proteins expressed in distal nephron epithelium; a vimentin expression pattern (Hes et al, 2007); c-KIT expression; S-100 (Pan et al, 2004; Lin et al, 2006; Hes et al, 2007; Li et al, 2007; Rocca et al, 2007; Lechpammer et al, 2008; Gupta et al, 2009; Osunkoya et al, 2009); NPM (nucleophosmin/B23) (Sari et al, 2012); and LMP2 (Zheng et al, 2013); or a combination of these markers (Kim et al, 2009). More recently, Ehsani and colleagues (2013) used immunohistochemistry to study the expression of BCA2, a RING E3 ligase, in patients with renal masses, and noted that 100% (114/114) of patients with RCC were negative for BCA2 expression, and 100% (38/38) of patients with oncocytomas were positive for BCA2 expression. An "optimal" panel for distinguishing between chromophobe and clear cell RCC and oncocytoma was recommended by Liu and colleagues in 2007, consisting of a combination of three markers (vimentin, glutathione-S-transferase- α , and epithelial cell adhesion molecule). These investigators achieved 100% sensitivity and 100% specificity for the differential diagnosis of chromophobe carcinoma, oncocytoma, and clear cell carcinoma (Liu et al, 2007). The feasibility of molecular signatures and gene profiling as potentially useful tests for the accurate diagnosis of tumors such as oncocytoma is being evaluated (Schuetz et al, 2005; Yang et al, 2006), but such studies are not yet a clinical reality.

As noted previously, there are several distinct similarities to chromophobe RCC, which also is derived from the distal renal tubules. Chromophobe RCC, particularly the eosinophilic variant, and oncocytoma are histologically similar and their distinction often requires additional pathologic testing (Weiss et al, 1995; Renshaw, 2002). The commonality of these two tumors is further evidenced in patients with Birt-Hogg-Dubé syndrome, in whom both oncocytomas and chromophobe RCC develop, in addition to cutaneous fibrofolliculomas and spontaneous pneumothoraces (Pavlovich et al, 2005; Toro et al, 2008). Some of the renal tumors display a histology between these two tumors, prompting some to speculate that chromophobe RCC and oncocytoma represent points in a spectrum of neoplasia (Chao et al, 2002; Linehan, 2003; Pavlovich et al, 2005; Toro et al, 2008).

The greatest clinical dilemma remains the inability to confidently differentiate between renal oncocytoma and RCC on clinical or radiographic testing. Both have a similar age at presentation with peak incidence in the seventh decade, have a 2:1 male-to-female predominance, and are similarly sized at presentation. Although oncocytomas traditionally were more likely to be asymptomatic at presentation, most RCC are also diagnosed incidentally in the current era, eliminating this clinical scenario as a differentiator (Davis et al, 1991; Licht et al, 1993; Lieber, 1993; Amin et al, 1997; Perez-Ordóñez et al, 1997; Dechet et al, 1999). The typical spoke-wheel pattern seen on angiography or the stellate scar on

cross-sectional imaging may bring up the question of a renal oncocytoma, but these findings have a poor predictive value by themselves (Davidson et al, 1993; Licht et al, 1993; Licht, 1995; Hilton, 2000; Choudhary et al, 2009). On CT scan, oncocytomas appear to have a high peak Hounsfield unit (HU) attenuation (similar to RCC); however, this peak has been found to occur more frequently during the nephrogenic phase (whereas in RCC it occurred more often in the corticomedullary phase) (Pierorazio et al, 2013). Conversely, other groups have found that segmental enhancement inversion on CT scan was not a reliable indicator of oncocytoma (McGahan et al, 2011; O'Malley et al, 2012). On MRI, oncocytomas may have distinct T1 and T2 signal patterns that can be suggestive, but these are not definitive findings (Harmon et al, 1996). T2-weighted images on MRI do not differentiate oncocytoma from RCC (Dann et al, 2006; Rosenkrantz et al, 2010). More recently, Cornelis and colleagues (2013) studied MRI in patients with oncocytoma or RCC and noted that complete late enhancement in the central area of the mass occurred more frequently in oncocytomas compared with RCC (74% vs. 12%, respectively), and that the absence of T2 signal intensity inversion or presence of signal drop on chemical-shift imaging could potentially rule out oncocytoma on MRI scans. For lesions undergoing surveillance, the growth rates of RCC and oncocytoma are similar, so growth kinetics also do not help differentiate these tumors (Chawla et al, 2006; Crispin and Uzzo, 2007; Siu et al, 2007; Kawaguchi et al, 2011). In 4% to 13% of patients, tumors are multicentric, are bilateral, or have a metachronous presentation (Lieber et al, 1987; Davis et al, 1991; Licht et al, 1993; Amin et al, 1997; Perez-Ordóñez et al, 1997; Dechet et al, 1999; Tickoo et al, 1999; Minor et al, 2003). The entity of renal oncocytomatosis, now referred to as *oncocytosis*, was first described by Warfel and Eble (1982) in a report of a patient with more than 200 oncocytomas in both kidneys. Familial renal oncocytomas was initially described (Weirich et al, 1998) in five families in which it presented at a young age as multicentric, bilateral, recurrent oncocytomas. Nonfamilial forms of bilateral multifocal oncocytomas resembling oncocytomatosis can also occur (Fig. 56-6). A recent cytogenetic evaluation of a patient with apparently sporadic oncocytomas and hybrid tumors showed different chromosomal losses than the Birt-Hogg-Dubé syndrome (Al-Saleem et al, 2004).

Historically, fine-needle aspiration or core biopsy was compromised by high rates of false-negative results and nondiagnostic specimens, given the difficulty in differentiating oncocytoma with RCC subtypes (Weiss et al, 1995; Campbell et al, 1997). However, the diagnostic accuracy of percutaneous biopsy has markedly improved, particularly when a core biopsy is done in addition to a fine-needle aspiration and is bolstered with the use of immunostains (Liu and Fanning, 2001; Barocas et al, 2006; Lebret et al, 2007; Volpe et al, 2007; Kummerlin et al, 2008; Schmidbauer et al, 2008), prompting some investigators to revisit the role of the biopsy in the management of some patients with an incidental renal tumor (Shah et al, 2005; Lebret et al, 2007; Volpe et al, 2007). When multiple tumors are present, one must consider the possibility of RCC coexisting with oncocytoma, the incidence of which in some series has been shown to be as high as 32% (Davis et al, 1991; Licht et al, 1993; Licht, 1995; Gudbjartsson et al, 2005). Biopsy in these patients must be thoughtfully considered to obtain a sampling of all sites of disease that are of concern.

Treatment options for a known oncocytoma range from observation to thermal ablation, laparoscopic or open partial nephrectomy, and even radical nephrectomy depending on the clinical scenario and uncertainty regarding the diagnosis (Licht, 1995; Romis et al, 2004; Gudbjartsson et al, 2005; Crispin and Uzzo, 2007). If oncocytoma is highly suspected and surgery is indicated, a nephron-sparing approach is preferred, given the benign nature of these lesions and the very low probability of recurrence (Licht, 1995; Romis et al, 2004; Gudbjartsson et al, 2005). Frozen section analysis is usually not sensitive enough to differentiate the eosinophilic appearance of oncocytomas from eosinophilic RCC and should not be used to guide surgical strategy. Thermal ablation, although sometimes reported as a treatment option, commits the

Figure 56-6. Computed tomography scan of a patient with multiple bilateral oncocytomas.
(Copyright 2009, S. F. Matin.)

patient to long-term radiographic surveillance, given the lower success rates of these procedures and the unknown long-term outcomes, tests that would be considered unnecessary should surgical excision be performed. In most cases the treatment options are isolated to observation, particularly for the older or sicker patient, and surgical resection, particularly for the younger healthier patient.

KEY POINTS: ONCOCYTOMA

- Renal oncocytoma is a common benign renal tumor that is clinically and radiographically indistinguishable from RCC.
- There may be a higher incidence of oncocytoma in older patients with a small renal mass as opposed to younger patients.
- Oncocytomas are derived from the distal renal tubules, similar to chromophobe RCC, and may represent a spectrum of neoplasia as evidenced in the Birt-Hogg-Dubé genetic syndrome. However, there is no evidence that oncocytomas undergo malignant transformation in sporadic cases.
- If oncocytoma is suspected preoperatively, a percutaneous core biopsy in addition to fine-needle aspiration may reliably provide a diagnosis when core tissue is available for additional immunohistochemical studies.
- Recent advancements in immunohistochemical markers have greatly improved the diagnostic accuracy of pathologic diagnosis from pathologic specimens and even core biopsy specimens.
- Frozen section analysis at the time of surgery may not reliably distinguish oncocytoma from RCC and should not be used to guide surgical strategy.

ANGIOMYOLIPOMA

Renal angiomyolipoma was originally described in 1900 by Grawitz (Grawitz, 1900). Angiomyolipoma accounts for less than 10% of renal tumors, with autopsy series and ultrasound-screened populations showing incidences of 0.3% and 0.13%, respectively, in the general population (Eble, 1998). It is a benign neoplasm; in its classic form it consists of thick-walled poorly organized blood vessels, smooth muscle, and varying levels of mature adipose tissue (Tamboli et al, 2000; Nelson and Sanda, 2002; Bissler and Kingswood, 2004). It was initially considered to be a form of hamartoma, but recent evidence suggests a neoplastic origin with evidence of a monoclonal, rather than polyclonal, source (Green et al, 1996; Sepp et al, 1996; Kattar et al, 1999). Angiomyolipoma is now considered to be derived from perivascular epithelioid cells, therefore belonging to a group of tumors referred to as *PEComas* (perivascular epithelioid cell tumors) (Bissler and Kingswood, 2004).

The tumor strongly expresses estrogen receptor β , progesterone receptor, and androgen receptor; is predominantly found in females; and is rare before puberty, suggesting a potential hormonal influence (Henske et al, 1998; L'Hostis et al, 1999; Boorjian et al, 2008).

Genetic studies in patients with tuberous sclerosis complex (TSC) resulted in discovery of two genes associated with angiomyolipomas: *TSC1* on chromosome 9q (encoding for hamartin protein) and *TSC2* on chromosome 16p (encoding for tuberlin protein) (European Chromosome 16 Tuberous Sclerosis Consortium, 1993; Henske et al, 1995; van Slegtenhorst et al, 1997). In sporadic TSC patients, 10% had *TSC1* mutations, 68% had *TSC2* mutations, and 22% had no mutations detected (Jones et al, 1999; Dabora et al, 2001).

The typical sporadic presentation is of a middle-aged woman with a single asymptomatic tumor. Sporadic angiomyolipomas appear to have a slow growth rate and are usually detected incidentally (Seyam et al, 2008). **Angiomyolipoma is the most common renal neoplasm associated with spontaneous perirenal hemorrhage, closely followed by RCC (Zhang et al, 2002).** Skolarus and colleagues (2008) suggested that there may be a decreased incidence of sporadic angiomyolipoma with increasing age. These tumors are most often sporadic but can also be associated with autosomal dominant TSC. **Twenty percent to 30% of angiomyolipomas occur in patients with TSC, and approximately 50% of patients with TSC develop angiomyolipomas (Eble, 1998; Neumann et al, 1998; Tamboli et al, 2000; Lendvay and Marshall, 2003; Minor et al, 2003).** TSC-associated angiomyolipomas typically manifest at a younger age (mean age 30 years); there is less female-to-male predominance (2:1) with multiple, bilateral, and symptomatic tumors (Eble, 1998; Neumann et al, 1998; Lendvay and Marshall, 2003). Because of the variable penetrance of the TSC mutation, the classic triad of seizures, adenoma sebaceum, and mental retardation may not be present because this mutation is seen in a minority of patients (Steiner et al, 1993). Patients with TSC also develop renal cysts and may be at higher risk of developing RCC. Lymphangioleiomyomatosis is also significantly associated with renal involvement in TSC (Rakowski et al, 2006).

Similar to RCC, most angiomyolipomas are now diagnosed incidentally during workup of unrelated complaints (Lemaitre et al, 1997; Seyam et al, 2008). The literature correlating tumor size and symptoms, however, is derived from before this era, when most angiomyolipomas were diagnosed after the development of symptoms. The Wunderlich syndrome, or massive retroperitoneal hemorrhage, representing the most significant complication of renal angiomyolipoma, was reported in up to 10% of patients and could be associated with significant morbidity and potential mortality if not promptly treated (Oesterling et al, 1986; Steiner et al, 1993; Eble, 1998). Pregnancy appears to increase the risk of hemorrhage from angiomyolipoma, a factor that can influence clinical decision making (Eble, 1998).

Figure 56-7. A, Computed tomography scan demonstrating large bilateral renal angiomyolipomas in a patient with tuberous sclerosis. B, Renal angiogram shows increased vascularity and aneurysmal dilation characteristic of angiomyolipoma. C, Typical microscopic appearance of angiomyolipoma with admixture of mature adipose tissue, smooth muscle, and thick-walled blood vessels.

Angiomyolipoma is the only benign renal tumor that is confidently diagnosed on cross-sectional imaging (Fig. 56-7). The presence of fat (confirmed on nonenhanced thin-cut CT by a value of -20 HU or less) within a renal lesion is considered the diagnostic hallmark (Jinzaki et al, 1997; Lemaitre et al, 1997; Bosniak et al, 1998; Simpfendorfer et al, 2009). Recently a study using a cutoff value of -10 HU showed an area under the curve of 0.83 for diagnosis of angiomyolipoma (Davenport et al, 2011). Findings of more than 20 pixels with attenuation less than -20 HU and of more than 5 pixels with attenuation less than -30 HU have been shown to have a positive predictive value of 100% (Simpfendorfer et al, 2009). Ultrasonography shows a well-circumscribed, highly echogenic lesion with shadowing (Siegel et al, 1996; Lemaitre et al, 1997). On angiography (or CT-angiography) aneurysmal dilation is found in 50% of angiomyolipomas (Lemaitre et al, 1997). The size of the aneurysms has been reported to correlate with the risk of rupture (Yamakado et al, 2002). MRI can be used in difficult cases, when the lesion has minimal fat, or in lieu of CT, with angiomyolipomas appearing hypointense on fat-suppressed T1 sequencing. In addition, angiomyolipoma appear hyperintense on T1 and T2 sequences as a result of their fat content (Kim et al, 2006; Halpenny et al, 2010).

Despite the radiographic hallmarks of angiomyolipoma, the diagnosis can be difficult to make in the three following situations: confusion with liposarcoma, possibility of fat-containing RCC, and possibility of a fat-poor angiomyolipoma resembling an RCC. Large angiomyolipomas can be confused with retroperitoneal liposarcomas, which are very rare. A good-quality, high-resolution CT, however, will invariably show several features that are characteristic of angiomyolipoma, the primary one being a small indentation of the renal parenchyma even when the tumor envelops

Figure 56-8. Computed tomography scan of angiomyolipoma with parenchymal indentation. (Copyright 2009, S. F. Matin.)

the kidney (Fig. 56-8), whereas liposarcomas will compress or only extrinsically push the renal parenchyma (Clark and Novick, 2001; Wang et al, 2002). Although RCC containing fat density has also been reported, these extremely rare cases also contained calcifications, a finding almost never seen with angiomyolipoma (Henderson et al 1997; Lemaitre et al, 1997; Roy et al, 1998). Most recently,

two cases of RCC with very small amounts of intratumoral fat but without calcification were reported, adding to two other reported cases in the literature (Hayn et al, 2009). Fat-poor angiomyolipoma, seen in 14% or more of patients, is much more difficult to diagnose, owing to the paucity of mature adipose tissue (Lemaitre et al, 1997; Kim et al, 2004; Milner et al, 2006). Lane and colleagues (2008a) showed that fat-poor angiomyolipoma was more commonly single, smaller, and found in older patients. Various imaging modalities have attempted to accurately identify these lesions preoperatively and differentiate them from RCC, with mixed success. On CT many appear to have hyperattenuation on noncontrast imaging and have a homogeneous and prolonged enhancement pattern (Jinzaki et al, 1997; Kim et al, 2004; Hafron et al, 2005; Milner et al, 2006; Silverman et al, 2007). Detailed pixel distribution analysis cannot differentiate between fat-poor angiomyolipoma and RCC (Catalano et al, 2008). Ultrasonography can show a hyperechoic or isoechoic lesion, suggesting a fat-poor angiomyolipoma (Jinzaki et al, 1997). Because of the nonspecific nature of these findings most patients are often treated as having a presumed RCC. However, these radiographic findings may prompt the attentive urologist to consider a percutaneous biopsy if the suspicion is raised by imaging. Percutaneous biopsy can play an important role in diagnosis in these patients because a core biopsy should be eminently accurate in the diagnosis of angiomyolipoma (Lebret et al, 2007; Silverman et al, 2007), especially when supplemented with immunohistochemical staining for HMB-45 protein (Pea et al, 1991). Epithelial markers should be negative in a typical angiomyolipoma (L'Hostis et al, 1999).

Although an invariably benign nature of angiomyolipoma is well accepted, extrarenal occurrences are occasionally seen and have been reported in the hilar lymph nodes, retroperitoneum, and liver, with direct extension into the venous system (Eble, 1998; Türker Köksal et al, 2000; Göğüş et al, 2001; Nelson and Sanda, 2002; Lin et al, 2003; Bissler and Kingswood, 2004; Akcali et al, 2006; Haritharan et al, 2006; Blick et al, 2008; Schade et al, 2008). Even in these patients a benign clinical course follows, indicating multicentric origin rather than malignancy with metastasis. Many angiomyolipomas exhibit regions of cellular atypia, and the pathologic differential diagnosis can include a number of subtypes of sarcoma, including fibrosarcoma, leiomyosarcoma, and liposarcoma, depending on the relative amounts of adipose, vascular, or smooth muscle tissue present (Wang et al, 2002). Positive immunoreactivity for HMB-45 (human melanoma black 45), a monoclonal antibody raised against a melanoma-associated antigen, is characteristic for angiomyolipoma and can be used to differentiate this tumor from sarcoma and other tumors (Eble, 1998), even on biopsy specimens. There have been two reports of high-grade and eventually lethal leiomyosarcoma arising within an angiomyolipoma. Christiano and colleagues (1999) have described a highly pleomorphic angiomyolipoma that was associated with the development of multiple pulmonary nodules, the majority of which stained positive for HMB-45 (Ferry et al, 1991). They believed that this case represented a malignant transformation of angiomyolipoma, which, if it does occur, must be exceedingly rare. However, these cases may also have represented the entity of epithelioid angiomyolipoma described by Mai and colleagues (1996). In 1997 Eble and colleagues published a report of their experience with five patients who had angiomyolipoma with a predominant epithelioid component (Eble et al, 1997); more recently, this malignant epithelioid variant of angiomyolipoma that can metastasize has been further described in patients with and without TSC, many of whom succumbed to the disease (Pea et al, 1998; L'Hostis et al, 1999; Martignoni et al, 2000; Cibas et al, 2001; Menè et al, 2001; Nelson and Sanda, 2002; Saito et al, 2002; Bissler and Kingswood, 2004; Huang et al, 2007; Limaïem et al, 2008; Matsuyama et al, 2008; Moudouni et al, 2008; Zanelli et al, 2008; Kato et al, 2009). This phenotype is characterized by epithelioid cells that are cytokeratin negative and HMB-45 positive. Whether this extremely rare variant represents malignant degeneration of a preexistent angiomyolipoma or a de novo tumor without a benign precursor remains unknown.

For optimal management of angiomyolipoma, treatment must be individualized. The management should take into account the size of the tumor, presence of symptoms, and patient factors. In particular, the risk of hemorrhage must be weighed during the evaluation. In general, most symptomatic angiomyolipomas have been relatively large and most studies in the literature have focused on a 4-cm cut point (Steiner et al, 1993; Nelson and Sanda, 2002). On the basis of an extensive literature review, Oesterling and coworkers (1986) reported that 82% of patients with angiomyolipomas larger than 4 cm in diameter were symptomatic, with 9% in hemorrhagic shock at the time of presentation; in contrast, patients with smaller tumors were symptomatic 23% of the time. Echoing these findings, Dickinson and colleagues (1998) reported that all 18 patients with angiomyolipomas smaller than 4 cm in their series were asymptomatic, whereas 7 of 13 patients with angiomyolipomas of 4 to 8 cm and 5 of 6 patients with tumors larger than 8 cm required intervention, primarily related to pain or bleeding. These observations have been confirmed and extended by a number of investigators (Blute et al, 1988; Steiner et al, 1993; Lemaitre et al, 1995; De Luca et al, 1999; Seyam et al, 2008). Steiner and colleagues (1993) reported that patients with angiomyolipomas larger than 4 cm were symptomatic 52% of the time, with 30% requiring surgical intervention, whereas patients with smaller tumors never required surgery and were asymptomatic 76% of the time. Although it was primarily retrospective, limited follow-up with a mean of 4 years was available for 24 patients with 28 tumors in this series. Interval growth was documented in 6 of 13 tumors with diameter of more than 4 cm and in 4 of 15 tumors smaller than 4 cm. A slower growth rate and a low risk of hemorrhage for smaller tumors were also supported by Kennelly and colleagues (1994), who observed 17 angiomyolipomas with tumor size of less than 4 cm for a mean of 3.8 years. Similarly, De Luca and colleagues (1999) studied 32 incidentally discovered angiomyolipomas smaller than 5 cm in diameter and found that 92% remained asymptomatic and unchanged in size. Even so, occasional larger angiomyolipomas undergoing observation, some for up to 18 years, can remain asymptomatic (Kennelly et al, 1994; Hadley et al, 2006; Danforth et al, 2007), reinforcing the concept that size represents a continuum of risk, not an absolute phenomenon, and highlighting the need for individualized tailoring of treatment recommendations. Multifocal angiomyolipomas and those in patients with tuberous sclerosis represent a special group that has demonstrated increased growth rates of approximately 20% per year, in contrast to a mean growth rate of 5% per year for solitary, sporadic angiomyolipomas (Steiner et al, 1993; Nelson and Sanda, 2002; Harabayashi et al, 2004; Seyam et al, 2008).

Although no large prospective studies evaluating the long-term outcomes of angiomyolipomas have been performed, the information reviewed here allows one to propose general guidelines for management. Asymptomatic, smaller tumors, which by convention have been those with a diameter less than 4 cm, can be observed expectantly, with repeat initial imaging at 6 to 12 months to define the growth rate and clinical significance. Repeat imaging can be lengthened once stability has been established, with follow-up performed only annually or biannually for smaller tumors (Oesterling et al, 1986; De Luca et al, 1999; Matin et al, 2008). Intervention should be considered for larger tumors, particularly if the patient is symptomatic, taking into account the patient's age, comorbidities, and other related factors. In women of childbearing age and patients with limited access to surveillance or to emergency care, a proactive approach should also be considered (Nelson and Sanda, 2002). A nephron-sparing approach, by either selective embolization or open or laparoscopic or robotic partial nephrectomy, is clearly preferred to radical nephrectomy in patients with angiomyolipomas requiring intervention. Preservation of renal tissue remains a priority in those with TSC or multicentric angiomyolipoma and particularly in patients with underlying renal insufficiency. The feasibility and efficacy of partial nephrectomy by either wedge resection or enucleation in patients with angiomyolipoma is well established, with preservation of renal function achieved even in patients with large lesions in a solitary kidney.

(Fazeli-Matin and Novick, 1998; Boorjian et al, 2007; Minervini et al, 2007). Selective embolization is reported by some to be the preferred modality, and data from 76 patients in six series have documented long-term success in most patients (Nelson and Sanda, 2002; Harabayashi et al, 2004). However, a substantial proportion of patients experienced persistent or recurrent symptoms or hemorrhage, and most of these required repeated procedures, including embolization or surgery (Hamlin et al, 1997; Han et al, 1997; Kehagias et al, 1998; Mourikis et al, 1999; Nelson and Sanda, 2002; Lenton et al, 2008). The overall complication rate with embolization in these series was 10%, similar to rates of partial nephrectomy (Boorjian et al, 2007), and included hemorrhage, abscess formation, or sterile liquefaction of the tumor requiring percutaneous drainage or surgical intervention. These data highlight the need for extended follow-up after selective embolization, which would not be required after partial nephrectomy (Nelson and Sanda, 2002). Selective embolization should be considered as first-line therapy in patients with acute or potentially life-threatening hemorrhage, because surgical exploration in this setting is often associated with total nephrectomy (Pappas et al, 2006; Chang et al, 2007). Ablative therapies such as radiofrequency ablation (Prevoo et al, 2008) and cryoablation (Bachmann et al, 2005; Byrd et al, 2006; Littrup et al, 2007; Caviezel et al, 2008) have also been used for the treatment of angiomyolipoma, but follow-up remains short, the evaluation of success remains poorly defined, and the duration for continued radiographic surveillance is unknown, thus committing the patient to multiple, long-term imaging. Ablative therapies may have their best role for the treatment of patients with TSC who have multicentric angiomyolipomas or older patients with comorbidities who require treatment and are not candidates for embolization.

Research into the molecular aspects of renal angiomyolipomas in patients with TSC showed a link between loss of TSC2 protein as a result of TSC2 mutation and activation of the mammalian target of rapamycin (mTOR) pathway (by demonstrating presence of S6K and phosphor-S6K in angiomyolipoma tissues) (El-Hashemite et al, 2003). Consequently, sirolimus was investigated in a phase 2 trial in 16 patients and showed an impressive response rate of 50% (using Response Evaluation Criteria in Solid Tumors [RECIST]) in the size of angiomyolipomas (Davies et al, 2011). Sirolimus was used in a neoadjuvant fashion in three patients with TSC with angiomyolipomas not amenable to surgical resection; after sirolimus treatment, tumor volume shrinkage of 38% to 95% was seen, and partial nephrectomy subsequently became feasible in all three patients (Staehler et al, 2012). Recently, everolimus was studied in a phase 3 trial in this patient setting and showed a response rate of 44% in angiomyolipomas (all measured at least 3 cm at study entry) (Bissler et al, 2013). This exciting research has led to a massive jumpstart of many clinical trials, several still ongoing, using mTOR inhibitors in patients with TSC and angiomyolipomas.

KEY POINTS: ANGIOMYOLIPOMA

- Angiomyolipoma is the only benign renal tumor confidently diagnosed on cross-sectional imaging by the presence of fat on nonenhanced thin-cut CT. Fat-poor angiomyolipoma may still be confused with RCC, but if it is suspected preoperatively then percutaneous biopsy is eminently capable of providing the diagnosis, with positivity for HMB-45 typically seen with angiomyolipoma.
- Angiomyolipoma is the most common renal tumor associated with spontaneous hemorrhage, followed by RCC.
- Treatment must be individualized based on the presentation, pregnancy status, tumor size, and renal function.
- The treatment of choice in patients with acute hemorrhage is selective renal angioembolization.
- Treatment options for elective management of larger angiomyolipomas include selective renal angioembolization and open or minimally invasive partial nephrectomy. Embolization is associated with a high rate of secondary procedures.

MIXED MESENCHYMAL AND EPITHELIAL TUMORS

Although considered separate entities by the 2004 World Health Organization classification of renal neoplasms, cystic nephroma and mixed epithelial and stromal tumors of the kidney (MESTs) are rare benign renal neoplasms that have overlapping clinical, morphologic, and immunohistochemical characteristics (Lopez-Beltran et al, 2006; Turbinder et al, 2007; Montironi et al, 2008). Recent demonstration of striking similarities between global gene expression profiles in cystic nephroma and MEST further strengthens the notion that these two entities represent opposite ends of the spectrum of the same biologic process (Zhou et al, 2009). Female predilection and history of hormonal ablation therapy in male patients, combined with the frequent expression of estrogen and progesterone receptors, suggest that the sex-steroid hormones might play a role in the pathogenesis of these rare lesions (Turbinder et al, 2007; Montironi et al, 2008; Stamatiou et al, 2008).

CYSTIC NEPHROMA

Cystic nephroma is a characteristic renal lesion with a bimodal age distribution and a benign clinical course (Tamboli et al, 2000). Diagnostic peaks occur primarily in the first 2 to 3 years of life, predominantly in boys, and again in the fourth and fifth decades with a significant (8:1) female prevalence (Madewell et al, 1983; Upadhyay and Neely, 1989; Castillo et al, 1991; Kuzgunbay et al, 2009; Stamatiou et al, 2008). As with other renal lesions, presenting signs can include abdominal mass, pain, and hematuria, but the majority of cystic nephromas are incidental findings (Madewell et al, 1983; Kuzgunbay et al, 2009). Several familial cases have been reported in the literature, and there have been anecdotal reports of sarcoma and clear cell carcinoma arising from cystic nephroma (Bal et al, 2005; Omar et al, 2006; Raj et al, 2006; Ashley and Reinberg, 2007).

Radiologically, most cystic nephromas are solitary, centrally located, and widely variable in size (mean size 9 cm) and commonly demonstrate curvilinear calcifications, herniation into the renal collecting system, and septal enhancement (Fig. 56-9A and B) (Madewell et al, 1983; Turbinder et al, 2007). Consequently, reliable radiologic differentiation between cystic nephroma and cystic RCC in adults or Wilms tumor in children is not possible (Vujanic et al, 2000).

Histologically, cystic nephromas are well encapsulated by a thick fibrous pseudocapsule and are composed of cysts lined by flattened, cuboidal, or hobnail epithelium (see Fig. 56-9C). The stromal component can range from dense paucicellular collagen to markedly cellular fascicles of spindle cells, closely resembling ovarian stroma (Tamboli et al, 2000). Immunohistochemical studies reveal affinity of the epithelial component for cytokeratins, whereas stromal components frequently stain positive for CD10, calretinin, inhibin, estrogen, and progesterone receptors (Turbinder et al, 2007; Montironi et al, 2008).

Because of concern for cystic Wilms tumor, most children with cystic nephromas continue to be managed by radical nephrectomy, whereas a nephron-sparing approach with partial nephrectomy, if feasible, is an attractive option in adults.

MIXED EPITHELIAL AND STROMAL TUMORS

MEST is a rare benign adult renal neoplasm with a variable admixture of epithelial and mesenchymal components (Pawade et al, 1993; Adsay et al, 2000). Previously these tumors were described as congenital mesoblastic nephroma, leiomyomatous renal hamartoma, solid and cystic biphasic tumor, cystic hamartoma, solitary multilocular cyst, and adult metanephric stromal tumor (Adsay et al, 2000; Pierson et al, 2001; Mai et al, 2007). Similar to cystic nephromas, MEST exhibits striking female predominance with a diagnostic peak in the fifth decade (mean age 46 years old). The majority of women diagnosed with MEST had

Figure 56-9. Cystic nephroma. Computed tomography (A) and magnetic resonance imaging (B) scans do not allow reliable distinction from cystic renal cell carcinoma or cystic Wilms tumor. C, The variably sized cystic spaces are lined by flattened epithelium (low magnification). (Copyright 2009, V. Margulis.)

a history of receiving estrogen replacement therapy, and the only male patient in the largest MEST series had a long history of androgen deprivation therapy for prostate cancer (Adsay et al, 2000). Presenting signs and symptoms of MEST are similar to those of cystic nephroma, with the majority detected incidentally (Adsay et al, 2000; Turbiner et al, 2007; Montironi et al, 2008).

Radiologic appearance of MEST is of a complex cystic renal mass, typically classified as Bosniak class III to IV lesions, indistinguishable from cystic RCC (Fig. 56-10A) (Adsay et al, 2000). A typical MEST has a benign clinical course, but recently a case of malignant transformation to a sarcomatoid carcinoma and several cases of local recurrence of a malignant stromal component with a dismal clinical course have been described (Adsay et al, 2000; Nakagawa et al, 2004).

Grossly, MEST appears encapsulated and ranges from 2 to 24 cm (mean 6 cm) (Adsay et al, 2000; Mai et al, 2007). Involvement of renal hilum and compression of the pelvicalyceal system is common, but gross infiltration of adjacent renal parenchyma is not seen (see Fig. 56-10B). The mesenchymal component is characterized by spindle cells showing variable degrees of smooth muscle, fibroblastic, or myofibroblastic differentiation with interspersed collagen bundles. The epithelial components vary from regular tubules to complex tubulopapillary structures with or without cystic dilatation, lined by cuboidal to flattened epithelium that may show clear cell changes and have a characteristic hobnail appearance (see Fig. 56-10C) (Adsay et al, 2000; Antic et al, 2006; Turbiner et al, 2007; Montironi et al, 2008). As in cystic nephroma, the epithelial components stain positive for cytokeratins whereas estrogen and progesterone receptor staining has been observed in the majority of the mesenchymal elements of MEST (Adsay et al, 2000).

A preoperative diagnosis of MEST should be considered in perimenopausal women receiving hormone therapy; however, because radiologic differentiation from RCC is not reliable, surgical intervention, preferably with a nephron-sparing approach, should be offered to appropriately selected patients.

KEY POINTS: CYSTIC NEPHROMA AND MIXED EPITHELIAL-STROMAL TUMOR

- These tumors are at opposite ends of the spectrum of the same biologic process with overlapping clinical, morphologic, and immunohistochemical characteristics.
- There is a female predilection, and a history of hormonal ablation therapy is noted in male patients.
- Frequent expression of estrogen and progesterone receptors in tumor tissue is reported.
- Clinical distinction from RCC or cystic Wilms tumor is not possible.
- If feasible, a nephron-sparing approach with partial nephrectomy is the preferred management strategy.

LEIOMYOMA

Leiomyomas are rare, benign tumors that may arise from smooth muscle cells anywhere along the genitourinary tract (Tamboli et al, 2000). In the kidney these tumors most commonly arise from the renal capsule, but renal pelvis and renal vein sites of origin have been reported (Wells et al, 1981; Steiner et al, 1990; O'Brien et al, 1992; Rao et al, 2001). Leiomyomas are found at autopsy with a frequency of 4.2% to 5.2%, but only a minority are discovered clinically, representing approximately 1.5% of all benign renal tumors treated surgically (Romero et al, 2005). As with other renal lesions, in the age of widespread use of CT abdominal imaging, the vast majority of leiomyomas are found incidentally (Romero et al, 2005; Derchi et al, 2008).

Renal leiomyomas have a characteristic appearance of a small exophytic renal mass with or without enhancement arising from renal capsule, but conclusive radiologic differentiation from RCC is not possible (Fig. 56-11A) (Steiner et al, 1990; Derchi et al, 2008).

Grossly, leiomyomas are firm, well encapsulated solid lesions. Histologic examination reveals intersecting fascicles of smooth muscle with no evidence of hypercellularity, pleomorphism, mitotic

Figure 56-10. Mixed epithelial and stromal tumor. A, Computed tomography scan characteristics are not distinguishable from renal cell carcinoma. B, Gross photograph of a partial nephrectomy specimen demonstrating a well-circumscribed mass composed of variably sized cysts separated by thick white septa. C, Medium-power magnification shows cysts lined by hobnail cells and spindle cell stroma. (Copyright 2009, V. Margulis.)

Figure 56-11. Renal leiomyoma. A, Computed tomography scan with characteristic appearance of a small renal mass arising from the renal capsule. B, Medium-power magnification shows uniform spindle cells with thin cigar-shaped nuclei, without any pleomorphism. C, Strong positive immunohistochemical staining with smooth muscle actin in the leiomyoma. Note lack of smooth-muscle actin staining in the normal renal tubules on the right. (Copyright 2009, V. Margulis.)

activity, or necrosis (see Fig. 56-11B) (Steiner et al, 1990; Tamboli et al, 2000). Immunohistochemical stains confirm the smooth muscle nature of the tumor with strong diffuse positive staining for smooth muscle markers desmin and caldesmon (see Fig. 56-11C) (Romero et al, 2005). Some leiomyomas positively stain for HMB-45, suggesting a possible link to angiomyolipoma and other PComas (Bonsib, 1996). Large lesions have traditionally been managed with radical nephrectomy, but nephron-sparing approaches should be considered for peripherally located small lesions.

KEY POINTS: LEIOMYOMA

- The characteristic appearance is of a small solid renal mass arising from the renal capsule.
- Radiologic differentiation from RCC is not possible.
- Nephron-sparing approaches are preferred when technically possible.

OTHER BENIGN RENAL TUMORS

A multitude of rare benign tumors derived from the various mesenchymal components of the kidney have been described and include multiple histiotypes, such as hemangioma, lymphangioma, juxtaglomerular cell tumor, renomedullary interstitial cell tumor, intrarenal schwannoma, and solitary fibrous tumor (Ligato et al, 1999; Tamboli et al, 2000). Current radiologic methods do not allow for conclusive differentiation of these benign tumors from malignant renal lesions, and surgical excision is often needed for pathologic confirmation.

Hemangiomas are benign vascular tumors that affect young adults with no gender predilection. These tumors are typically single and unilateral and for the most part occur close to the renal pyramids and pelvis. They do not have a capsule and they appear spongy red, with irregular vascular spaces lined by a single-cell endothelial layer (Tamboli et al, 2000). Renal hemangiomas are commonly sporadic but can also occur with syndromes such as Klippel-Trenaunay, Sturge-Weber, and systemic angiomas.

Lymphangiomas are rare benign tumors arising from the renal capsule and growing as a renal sinus mass or peripelvic mass. Some patients exhibit genetic abnormalities such as trisomy 7, monosomy X, and *VHL* abnormalities (Debiec-Rychter et al, 1990; Caduff et al, 1997). Lymphangiomas are encapsulated, diffusely cystic, with communicating cysts composed of fibrous septations lined by flat endothelium.

Juxtaglomerular cell tumor (also known as *reninoma*) is a benign tumor of the renal juxtaglomerular cell apparatus (Robertson et al, 1967; Wong et al, 2008). With fewer than 100 cases reported in the literature, women in the third and fourth decades are most commonly affected (Martin et al, 2001; Rubenstein et al, 2002; Wong et al, 2008). **Clinical presentation is dominated by hypersecretion of renin and includes hypertension and hypokalemia and associated symptoms such as polydipsia, polyuria, myalgia, and headaches** (Schonfeld et al, 1991; Rubenstein et al, 2002). Laboratory testing usually reveals elevated plasma renin activity, secondary hyperaldosteronism, hypokalemia, and a solitary renal lesion. The radiologic appearance is that of a small (<3 cm) solid hypovascular renal mass; and surgical excision, preferably sparing the remaining renal parenchyma, results in rapid decline of plasma renin levels, normalization of blood pressure, and resolution of the associated symptoms (Dunnick et al, 1983; Schonfeld et al, 1991; Tanabe et al, 2001). Histologic examination reveals sheets of polygonal to spindle-shaped cells with indistinct cell borders, abundant eosinophilic cytoplasm, and minimal atypia (Martin et al, 2001). Strong immunostaining for factor VIII and factor VIII-related antigens is characteristic and confirms derivation from endothelial cell lineage (Sanfilippo et al, 1982). Cells will also stain for renin, CD34, vimentin, and actin (Martin et al, 2001).

Although a benign clinical course is expected, one case of malignant reninoma has been documented in the literature (Duan et al, 2004).

Renomedullary interstitial cell tumors are commonly seen at autopsy (Reese and Winstanley, 1958), measure less than 5 mm in size, and are typically asymptomatic, without any effect on blood pressure. Cells are polygonal or stellate in a basophilic stroma and contain minimal collagen.

Intrarenal schwannoma is very rare, with fewer than 20 cases reported. Tumors cause nonspecific signs and symptoms, are well encapsulated, and are composed of spindle cells in a palisading format (Singer and Anders, 1996; Alvarado-Cabrero et al, 2000).

Solitary fibrous tumor is a clinically important entity, as it tends to manifest as a large mass with gross hematuria and could be mistaken for RCC or sarcoma. It is a rare tumor, reported in fewer than 50 patients to date (Khater et al, 2013). Tumors arise from the renal parenchyma, are well circumscribed, and consist of bland spindle cells and collagenous bands. Typically, staining for CD34, CD99, and BCL-2 ascertains the diagnosis of solitary fibrous tumor (Wang et al, 2001; Magro et al, 2002).

KEY POINTS: OTHER BENIGN RENAL TUMORS

- Numerous rare benign tumors derived from the various mesenchymal components of the kidney have been described.
- Radiologic differentiation from renal malignancy is not possible.
- Reninoma, a benign tumor of the renal juxtaglomerular cell apparatus, is an important but rare cause of secondary hypertension and hypokalemia.

Treatment of Locally Advanced Renal Cell Carcinoma

Other Malignant Renal Tumors

HISTORICAL CONSIDERATIONS

The introduction of nephrectomy and other surgeries for renal diseases provided the clinical information and histopathologic insight that form the basis of current concepts regarding renal tumors. The first documented nephrectomy was accomplished in 1861 by Wolcott, who operated with the mistaken assumption that the tumor mass was a hepatoma. In 1867, Spiegelberg removed a kidney incidentally in the course of excising an echinococcus cyst. The first planned nephrectomy was performed by Simon in 1869 for persistent ureteral fistula, and this patient survived with cure of the fistula. One year later (1870), the first planned nephrectomy in the United States was successfully accomplished by Gilmore in Mobile, Alabama, for treatment of atrophic pyelonephritis and persistent urinary tract infection (Herr, 2008). Harris (1882) subsequently reported on 100 surgical extirpations of the kidney, a sufficient number to permit analysis of clinical, surgical, and pathologic features of renal disorders that require surgery.

With surgical intervention, tissue became available to pathologists for histologic interpretation. Unfortunately, such interpretation was not always accurate, and there were often serious professional differences of opinion. According to Carson (1928), the first accurate gross description of kidney tumors dates to 1826, with König's observations. In 1855, Robin examined solid tumors apparently arising in the kidney and concluded that renal carcinoma arose from renal tubular epithelium. This interpretation was confirmed by Waldeyer in 1867. Unfortunately, theoretical and practical considerations of renal tumors were confused by Grawitz (1883), who contended that such apparent renal tumors arose from adrenal rests within the kidney. He introduced the terminology *struma lipomatodes aberrata renis* as descriptive nomenclature for the tumors of clear cells that he believed were derived from the adrenal glands. He based his conclusions not only on the fatty content of the tumors, analogous to that seen in the adrenal glands, but also on the location of the tumors beneath the renal capsule, the approximation to the adrenal glands, the lack of similarity of the cells to uriniferous tubules, and the demonstration of amyloid similar to that seen with adrenal degeneration.

This histogenetic concept was adopted by subsequent investigators, and pathologists of the era readily embraced the idea that renal tumors truly arose from the adrenal glands. In 1894, Lubarch endorsed the idea of a suprarenal origin of renal tumors, and the term *hypernephroid tumors*, indicating origin above the kidneys, was advocated by Birch-Hirschfeld (Birch-Hirschfeld and Doederlein, 1894). This semantic and conceptual mistake led to the introduction of the term *hypernephroma*, which predominated in the literature describing parenchymal tumors of primary renal origin. Some clarification of the histopathology of renal tumors was derived from the work of Albarran and Imbert (1903), and the four-volume

contribution of Wolff (1883), written between 1883 and 1928, added further historical significance to the understanding of renal tumors (Herr, 2008).

The modern era has brought an appreciation that renal cell carcinoma (RCC) includes a number of distinct subtypes derived from the various parts of the nephron, each with a unique genetic basis and tumor biology (Rini et al, 2009; Linehan and Ricketts, 2013). Other major advances in the past several decades have included the introduction of radical nephrectomy (RN) followed by a trend toward less radical approaches, including kidney-sparing surgery and a variety of minimally invasive approaches (Robson, 1963; Novick, 2007; Volpe et al, 2011). One common theme that has persisted is that RCC remains primarily a surgical disease and, although immune-based and targeted molecular approaches can provide durable clinical responses, cure is rarely seen without complete surgical excision of RCC (Rini et al, 2009; Kroeger et al, 2014). Unfortunately, the incidence of RCC is gradually increasing and, despite a trend toward earlier detection, mortality rates remain high.

CLASSIFICATION

Renal masses can be malignant, benign, or inflammatory as classified by Barbaric (1994) (Box 57-1), or they can be classified based on radiographic appearance (simple cystic, complex cystic, solid) (Box 57-2). These classification schemes have been updated based on current knowledge about the distinct subtypes of RCC and other benign and malignant tumors of the kidney (Eble et al, 2004; Algaba et al, 2011). Malignant renal tumors include RCC, urothelium-based malignancies, sarcomas, embryonic or pediatric tumors, lymphomas, and metastases. Benign renal tumors are diverse and present unique diagnostic challenges (see Chapter 56). Inflammatory and vascular lesions must also be considered in the differential diagnosis.

RADIOGRAPHIC EVALUATION OF RENAL MASSES

Several radiographic modalities are currently available for detection and evaluation of renal masses, each with relative strengths and limitations (Kang and Chandarana, 2012). A systematic approach is necessary to ensure diligent evaluation of suspected renal masses, given the large differential diagnosis and considerable overlap between benign and malignant renal lesions (Fig. 57-1; see Box 57-2) (Simmons et al, 2007).

Although intravenous pyelography was often the first test that indicated a renal mass in the past, it has now fallen out of favor (Kang and Chandarana, 2012). The lack of sensitivity

BOX 57-1 Renal Masses Classified by Pathologic Features**MALIGNANT**

Renal cell carcinoma
 Urothelium-based cancers
 Urothelial carcinoma
 Squamous cell carcinoma
 Adenocarcinoma
 Sarcomas
 Leiomyosarcoma
 Liposarcoma
 Angiosarcoma
 Hemangiopericytoma
 Malignant fibrous histiocytoma
 Synovial sarcoma
 Osteogenic sarcoma
 Clear cell sarcoma
 Rhabdomyosarcoma
 Wilms tumor
 Primitive neuroectodermal tumor
 Carcinoid tumor
 Lymphoma/leukemia
 Metastasis
 Invasion by adjacent neoplasm

BENIGN

Cystic lesions
 Simple cyst
 Hemorrhagic cyst

BENIGN—cont'd

Solid lesions
 Angiomyolipoma
 Oncocytoma
 Renal adenoma
 Metanephric adenoma
 Cystic nephroma
 Mixed epithelial-stromal tumor
 Reninoma (juxtaglomerular cell tumor)
 Leiomyoma
 Fibroma
 Hemangioma
 Vascular lesions
 Renal artery aneurysm
 Arteriovenous malformation
 Pseudotumor

INFLAMMATORY

Abscess
 Focal pyelonephritis
 Xanthogranulomatous pyelonephritis
 Infected renal cyst
 Tuberculosis
 Rheumatic granuloma

BOX 57-2 Radiologic and Pathologic Correlates for Renal Masses**SIMPLE CYSTIC**

Benign cyst
 Parapelvic cyst
 Hydronephrosis
 Caliceal diverticulum

COMPLEX CYSTIC

Cystic RCC
 Hemorrhagic cyst
 Hyperdense cyst
 Benign complex cyst
 Cystic nephroma
 Mixed epithelial-stromal tumor
 Cystic Wilms tumor
 Infected cyst/abscess
 Hydrocalix
 Arteriovenous malformation
 Renal artery aneurysm

STRONGLY ENHANCING SOLID MASS

Clear cell RCC
 Angiomyolipoma
 Oncocytoma (occasionally)
 Papillary RCC (occasionally)
 Chromophobe RCC (occasionally)

MODERATELY ENHANCING SOLID MASS

Papillary RCC
 Chromophobe RCC
 Oncocytoma
 Other benign tumors
 Fat-poor angiomyolipoma
 Adenoma
 Metanephric adenoma
 Unifocal lymphoma
 Sarcoma
 Lobar nephronia
 Infarct

MULTIFOCAL/BILATERAL MASSES

Familial RCC
 Metastases
 Sporadic, multifocal RCC
 Angiomyolipomas (tuberous sclerosis)
 Lymphoma
 Cystic tumors (autosomal dominant polycystic kidney disease)

INFILTRATIVE MASS

Lymphoma
 High-grade urothelial carcinoma
 Sarcomatoid differentiation
 Collecting duct carcinoma
 Renal medullary carcinoma
 Xanthogranulomatous pyelonephritis
 Metastasis (occasionally)

CALCIFIED MASS

RCC
 Urothelial carcinoma
 Benign complex cyst
 Xanthogranulomatous pyelonephritis
 Renal artery aneurysm
 Concomitant nephrolithiasis

FAT-CONTAINING MASS

Angiomyolipoma
 Liposarcoma
 Lipoma

RCC, renal cell carcinoma.

Modified from Simmons MN, Herts BR, Campbell SC. Image based approaches to the diagnosis of renal masses [lesson 39]. AUA Update Series 2007;26:382–91.

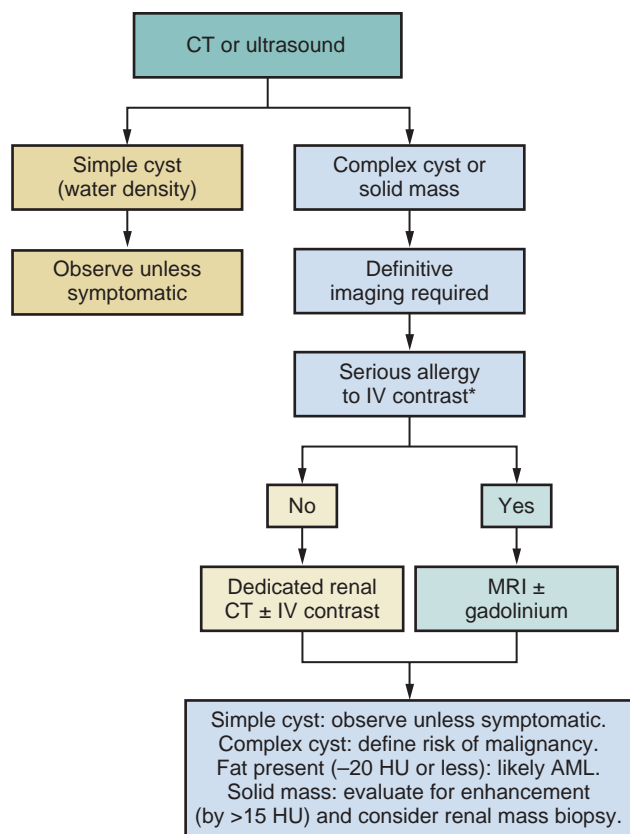

Figure 57-1. Algorithm for radiographic evaluation of renal masses. AML, angiomyolipoma; CT, computed tomography; HU, Hounsfield units; IV, intravenous; MRI, magnetic resonance imaging. *In the presence of chronic kidney disease, the risks of contrast nephropathy must also be weighed against those of nephrogenic systemic fibrosis associated with gadolinium administration.

and specificity of intravenous pyelography for the detection of parenchymal tumors is well documented. In particular, intravenous pyelography may miss small anterior or posterior lesions that do not distort the collecting system or contour of the kidney. Features suggestive of malignancy on intravenous pyelography include calcification within the mass, increased tissue density, irregularity of the margin, and distortion of the collecting system (Zagoria, 2000).

Ultrasonography is a noninvasive and relatively inexpensive modality that can differentiate cystic versus solid renal masses, and it continues to play an important role for such lesions. Strict ultrasonographic criteria for simple cysts have been defined and include a smooth cyst wall, a round or oval shape without internal echoes, and through-transmission with strong acoustic shadows posteriorly. If these criteria are met, observation is sufficient in an asymptomatic patient. In evaluating complex renal cysts, important ultrasonographic features include thickness and contour of the cyst wall, number and thickness of any septa, presence of any calcifications, density of cyst fluid, and presence of solid or nodular components. Ultrasonography is helpful in suggesting the fat content of an angiomyolipoma (AML) by its characteristic increased echogenicity (Nelson and Sanda, 2002). A renal mass that is not clearly a simple cyst by strict ultrasound criteria should be evaluated further with computed tomography (CT).

A dedicated renal CT scan remains the single most important radiographic test for delineating the nature of a renal mass. CT, with and without the administration of contrast material, is necessary to take full advantage of the contrast enhancement characteristics of highly vascular renal parenchymal tumors (Kang and Chandarana, 2012). In general, any renal mass that enhances with

Figure 57-2. A, Computed tomography (CT) scan without administration of contrast material shows solid, right posterior renal mass. B, After administration of the contrast agent, CT scan shows that the mass enhances more than 20 HU and is thus highly suggestive of renal cell carcinoma (RCC). This mass was excised and confirmed to be a clear cell RCC. (Courtesy Dr. Terrence Demos, Maywood, IL.)

intravenous administration of contrast material on CT by more than 15 Hounsfield units (HU) should be considered an RCC until proved otherwise (Fig. 57-2). Solid masses that also have substantial areas of negative CT attenuation numbers (below -20 HU) indicative of fat are diagnostic of AML (Nelson and Sanda, 2002). In 10% to 20% of solid renal masses, CT findings are indeterminate, and additional imaging, biopsy, or surgery is needed to establish a definitive diagnosis. On occasion, CT demonstrates an enhancing renal segment that is isodense with the remainder of the kidney, suggestive of a renal pseudotumor. In the latter instance, renal mass biopsy should be considered.

Magnetic resonance imaging (MRI) is the alternate standard imaging modality for the characterization of a renal mass (Kang and Chandarana, 2012; Donat et al, 2013). Enhancement indicative of malignancy can also be assessed by MRI with intravenous gadolinium-labeled diethylenetriaminepentaacetic acid, although the assessment is qualitative rather than quantitative (Fig. 57-3). This technique is most useful in patients for whom iodinated contrast medium is contraindicated because of severe allergy. One concern with MRI with gadolinium is the uncommon but potentially serious complication of nephrogenic systemic fibrosis, which is more common in patients with chronic kidney disease (CKD) (Bach and Zhang, 2008). Current recommendations are to avoid MRI with gadolinium, particularly serial studies, in this population whenever possible, and to dialyze patients after the study if end-stage renal disease is present. MRI without contrast can be performed in patients with CKD and a renal mass, but some radiologists prefer CT with intravenous contrast and careful periprocedural hydration; in either case, decision making must be individualized. Contrast-enhanced ultrasonography using microbubbles has also shown promise for the characterization and assessment of enhancement of renal masses and may play an important role in patients with CKD in the future (Simmons et al, 2007).

Renal arteriography has a limited role in the diagnostic evaluation of renal masses and is primarily reserved for patients with concomitant renal artery disease. In equivocal cases, the presence or absence of neovascularity may help establish the diagnosis of

Figure 57-3. Renal cell carcinoma on pre- and postcontrast magnetic resonance image (MRI) and contrast-enhanced computed tomography (CT). **A**, Precontrast, T2-weighted MRI showing a simple cyst in the right kidney and heterogeneous 8.5 cm, lower pole tumor in the left kidney. **B**, Postcontrast, fat-saturated, T1-weighted MRI reveals further anatomic details regarding the left renal tumor, including a tumor thrombus (arrow) within the renal vein not reaching the inferior vena cava. **C**, Contrast-enhanced CT imaging (parenchymal phase) from the same patient also shows the left renal tumor. MRI was performed in this patient because of equivocal findings on the initial CT scan regarding a renal vein thrombus, which was seen clearly on both pre- and postcontrast MRI. (Courtesy Dr. Leena Mammen, Grand Rapids, MI.)

RCC. However, 20% to 25% of RCCs are angiographically indistinct, even though most of these tumors are not truly avascular and demonstrate contrast enhancement by 10 to 25 HU on CT.

For radiographically detected solid renal masses, the differential diagnosis is extensive and includes conditions such as RCC, oncocytoma, AML, urothelial carcinoma, metastasis, abscess, infarct, vascular malformation, and renal pseudotumor (see [Box 57-2](#)). The diagnosis of most of these lesions can be established on the basis of clinical presentation and characteristic radiographic features, occasionally combined with endourologic studies or renal mass biopsy ([Dyer et al, 2008](#); [Kang and Chandarana, 2012](#)). However, it is often not possible to reliably distinguish RCC from benign renal neoplasms, including oncocytoma and fat-poor AML, with current diagnostic techniques. Ten to 20 percent of small, solid, CT-enhancing renal masses with features suggestive of RCC prove to be benign after surgical excision ([Corcoran et al, 2013](#)). Although oncocytoma is a benign tumor (see Chapter 56), it can be multifocal and is occasionally associated with RCC in the same or the opposite kidney ([Licht et al, 1993](#); [Dechet et al, 1999](#); [Adamy et al, 2011](#); [Boris et al, 2011](#); [Childs et al, 2011](#)).

Renal mass biopsy is now being revisited for the evaluation of renal masses ([Lane et al, 2008](#); [Samplaski et al, 2011](#); [Volpe et al,](#)

[2012](#)). Historically the false-negative rate of renal mass biopsy was thought to be 18%, too high to justify routine use. However, most of these “false negatives” were in reality instances in which the mass could not be adequately targeted or the material obtained was insufficient for the pathologist to make a definitive determination. Review of this literature has shown that, although about 15% of renal mass biopsy specimens are nondiagnostic, the real false-negative rate is now less than 1% ([Lane et al, 2008](#)). Overall accuracy is greater than 80%. Assessment of histologic type can be facilitated by selective use of immunohistochemical stains when microscopic features are not diagnostic, but nuclear grade at biopsy does not always correlate with the final grade at nephrectomy, in part due to tumor heterogeneity ([Ficarra et al, 2011](#); [Abel et al, 2012](#)). The risks of clinically significant perinephric bleeding and pneumothorax also appear to be low (<1%), and needle track seeding is exceedingly rare when centrally located, infiltrative renal masses are excluded. Poorly differentiated urothelial carcinoma is much higher risk for needle track seeding than RCC. Given the great heterogeneity in the tumor biology of enhancing clinical T1 renal masses, renal mass biopsy is now being considered more frequently, particularly in patients who are potential candidates for a wide variety of treatment options ranging from observation to

Figure 57-4. Bosniak category II renal cysts. A, Computed tomography (CT) scan shows right renal cyst with thin internal septation. B, CT scan in another patient shows relatively thin, curvilinear calcification in the septa of the wall of right renal cyst. C, CT scan without administration of contrast material shows small, smooth-walled, high-density left renal cyst. D, CT scan after administration of contrast material shows no enhancement of the cyst. This is an extreme example of a hyperdense cyst. (Courtesy Dr. Terrence Demos, Maywood, IL.)

surgical excision. Younger, healthy patients who are unwilling to accept the uncertainty associated with renal mass biopsy are still typically managed primarily based on radiographic and clinical considerations. More traditional indications for renal mass biopsy include suspicion of renal abscess or when RCC must be differentiated from metastatic malignant disease or renal lymphoma (Somani et al, 2007; Volpe et al, 2012).

Evaluation of Cystic Renal Lesions

The differentiation between benign renal cysts and cystic RCC remains one of the more common and difficult problems in renal imaging (Bosniak, 2012). When a complex renal cyst is identified, determination of its benign or malignant nature is based on evaluation of the wall of the lesion; its thickness and contour; the number, contour, and thickness of any septa; the amount, character, and location of any calcifications; the density of fluid in the lesion; the margination of the lesion; and the presence of solid components. Bosniak developed a useful classification scheme primarily based on CT imaging criteria that divides renal cystic lesions into categories that are distinct from one

another in terms of the likelihood of malignancy (Israel and Bosniak, 2005). Category I lesions are uncomplicated, simple, benign cysts of the kidney that are straightforward to diagnose on ultrasonography, CT, or MRI. These are by far the most common renal cystic lesions, and in the absence of associated symptoms, no treatment is necessary.

Category II lesions are minimally complex cysts that are generally benign but have some radiologic findings that cause concern (Fig. 57-4). These lesions include septated cysts, cysts with calcium in the wall or septum, infected cysts, and hyperdense (high-density) cysts (Israel and Bosniak, 2005). Hyperdense cysts are benign lesions that contain old, degenerated, or clotted blood; therefore, the CT attenuation of their contents is increased (>20 HU). Classic hyperdense renal cysts are small (<3 cm), round, and sharply margined and do not enhance after the administration of contrast material (see Fig. 57-4). This category has now been subdivided to differentiate category II lesions that do not require surveillance from category IIF lesions that mandate surveillance. The nuances involved in this classification are highlighted in Table 57-1. High-quality imaging, preferably CT, and considerable radiologic expertise are required to optimize the

TABLE 57-1 Classification of Complex Renal Cysts

BOSNIAK CLASSIFICATION	RADIOGRAPHIC FEATURES	RISK OF MALIGNANCY	MANAGEMENT
I	Water density Homogeneous, hairline thin wall No septa No calcification No enhancement	None	Surveillance not necessary
II	Few hairline septa in which “perceived” enhancement may be present Fine calcification or short segment of slightly thickened calcification in wall or septa No unequivocal enhancement Hyperdense lesion: ≤ 3 cm, well marginated, with no unequivocal enhancement	Minimal Minimal	Surveillance not necessary Periodic surveillance
IIF	Multiple hairline thin septa Minimal smooth wall thickening “Perceived” enhancement of wall or septae may be present Calcification may be thick or nodular, but must be without enhancement Generally well marginated No unequivocal enhancement Hyperdense lesion: >3 cm or totally intrarenal, with no enhancement	3%-5% 5%-10%	Periodic surveillance Periodic surveillance
III	“Indeterminate,” thickened irregular or smooth walls or septa in which measurable enhancement is present	50%	Surgical excision
IV	Clearly malignant lesions that can have all the criteria of category III but also contain enhancing soft-tissue components	75%-90%	Surgical excision

Figure 57-5. Bosniak category III cysts. A, Computed tomography (CT) scan shows complex right renal cyst with thick and irregular septa and inhomogeneous character. B, CT scan shows somewhat thick-walled, complex left renal cyst also exhibiting irregular calcification and moderate heterogeneity. (Courtesy Dr. Terrence Demos, Maywood, IL.)

characterization of complex renal cystic lesions. The risk of radiographic progression of category IIF lesions is about 15%, so these lesions should be observed with periodic renal imaging. Overall risk of malignancy in this category is 3% to 10%, although higher proportions of malignancy in surgically treated IIF lesions have been reported (O'Malley et al, 2009a; Smith et al, 2012; Graumann et al, 2013; El-Mokadem et al, 2014).

Category III lesions are more complex renal cysts that cannot be confidently distinguished from malignant neoplasms (Israel and Bosniak, 2005; Smith et al, 2012; Goenka et al, 2013). The radiographic features include thickened irregular or smooth walls or septa in which measurable enhancement can be observed (Fig. 57-5). In the absence of a mitigating factor such as renal trauma or infection, surgical exploration is usually indicated in

Figure 57-6. Bosniak category IV cysts. A, Computed tomography (CT) scan shows complex left renal cystic lesion with thick, enhancing walls. B, CT scan shows complex right cystic lesion with enhancing nodular areas and inhomogeneity. Both lesions proved to be renal cell carcinoma.

healthy patients. About 50% of these lesions are malignant; the remainder prove to be benign multiloculated, hemorrhagic, or densely calcified cysts (see [Box 57-2](#)). Fine-needle aspiration of complex cysts is rarely performed because of concern about sampling error and tumor cell spillage.

Category IV lesions have large cystic components; irregular, shaggy margins; and, most important, solid enhancing portions that provide a definitive diagnosis of malignancy ([Fig. 57-6](#)) ([Israel and Bosniak, 2005](#)). Category IV lesions are almost invariably cystic RCCs that, if localized, require surgical treatment.

RENAL CELL CARCINOMA

Incidence

RCC, which accounts for 2% to 3% of all adult malignant neoplasms, is the most lethal of the common urologic cancers. Five-year relative survival rates for patients diagnosed in 2002 to 2008 were 71% for kidney cancer, 78% for bladder cancer (excluding carcinoma in situ), and 99% for prostate cancer ([Siegel et al, 2013](#)). Approximately 65,000 new diagnoses of RCC are made each year in the United States, and 13,000 patients die of disease ([Siegel et al, 2013](#)). Overall, approximately 12 new cases are diagnosed per 100,000 population per year, with a male-to-female predominance of 3:2 ([Siegel et al, 2013](#)). This is primarily a disease of older adults, with typical presentation between 50 and 70 years of age ([Pantuck et al, 2001b](#); [Wallen et al, 2007](#); [Siegel et al, 2013](#)). However, diagnosis of renal cancer has increased more rapidly in those less than 40 years of age than any other age group ([Neppl et al, 2012](#)). Incidence rates are 10% to 20% higher and 5-year survival rates 5% lower in African-Americans for unknown reasons ([Lipworth et al, 2006](#); [Stafford et al, 2008](#); [Chow et al, 2013](#); [Siegel et al, 2013](#)). The majority of cases of RCC are believed to be sporadic; only 2% to 3% are proven to be familial ([Lipworth et al, 2006](#)).

The incidence of RCC has increased since the 1970s by an average of 3% to 4% per year, largely related to the more prevalent use of ultrasonography and CT for the evaluation of a variety of abdominal complaints ([Decastro and McKiernan, 2008](#); [Kümmeler et al, 2008](#)). This trend has correlated with an increased proportion of incidentally discovered and localized tumors and with improved 5-year survival rates for patients with this stage of disease ([Pantuck et al, 2001b](#); [Parsons et al, 2001](#); [Kane et al, 2008](#)). However, other factors must also be at play because a steadily increasing mortality rate from RCC per unit population has been observed in all ethnic groups and both genders since the 1980s ([Chow et al, 1999](#); [Siegel et al, 2013](#)). This rising mortality rate is particularly troubling because the proportion of advanced tumors has actually decreased ([Wallen et al, 2007](#); [Decastro and](#)

[McKiernan, 2008](#); [Siegel et al, 2013](#)). This suggests that a deleterious change in tumor biology may have occurred during the past several decades, perhaps related to tobacco use, dietary factors, or exposure to other carcinogens ([Pantuck et al, 2001b](#); [Parsons et al, 2001](#); [Hock et al, 2002](#); [Kane et al, 2008](#)).

RCC in childhood is uncommon, representing only 2.3% to 6.6% of all renal tumors in children ([Broecker, 2000](#)). Mean age at presentation in children is 8 to 9 years, and the incidence is similar in boys and in girls. Although Wilms tumor is much more common in younger children, RCC is as common as Wilms tumor during the second decade of life. RCC in children and young adults is more likely to be symptomatic, locally advanced, high grade, and of unfavorable histologic subtypes ([Sánchez-Ortiz et al, 2004b](#); [Estrada et al, 2005](#); [Cook et al, 2006](#)). TFE3 protein overexpression, which correlates with the presence of *ASPL-TFE3* and *PRCC-TFE3* gene translocation events involving the X and first chromosomes, is relatively common in children and young adults with RCC and is unique to this population ([Heimann et al, 2001](#); [Geller et al, 2008](#)). The clinical significance of TFE3 protein overexpression is not well defined, although preliminary data suggest that these tumors may show differential sensitivity to certain chemotherapeutic agents ([Heimann et al, 2001](#); [Argani et al, 2002](#); [Pérot et al, 2003](#); [Bruder et al, 2004](#)). A distinct pathologic subtype has been described in patients with TFE3 overexpression that exhibits both clear cell and papillary features ([Algaba et al, 2011](#)). Most studies suggest that stage for stage, children and young adults with RCC may respond better to surgical therapy, and a number of long-term survivors have been reported after RN and lymphadenectomy for lymph node–positive disease ([Abou El Fettouh et al, 2002](#); [Sánchez-Ortiz et al, 2004b](#); [Geller et al, 2008](#)). An aggressive surgical approach with formal lymphadenectomy has thus been recommended at the time of RN when RCC is suspected in children or young adults ([Selle et al, 2006](#); [Bosquet et al, 2008](#)).

Etiology

RCCs were traditionally thought to arise primarily from the proximal convoluted tubules, and this is probably true for the clear cell and papillary variants. However, we now know that other histologic subtypes of RCC, such as chromophobe RCC and collecting duct carcinoma, are derived from the more distal components of the nephron ([Pantuck et al, 2001a](#)). The most generally accepted environmental risk factor for RCC is tobacco exposure, although the relative associated risks have been modest, ranging from 1.4 to 2.5 compared with controls. All forms of tobacco use have been implicated, and risk increases with cumulative dose or pack-years. Relative risk is directly related to duration of smoking and begins to fall after cessation, further supporting a cause-and-effect relationship ([Parker et al, 2003b](#); [Hunt et al, 2005](#); [Ljungberg](#)

et al, 2011). Tobacco use accounts for 20% to 30% of cases of RCC in men and 10% to 20% in women.

Obesity is now accepted as another major risk factor for RCC, with an increased relative risk of 1.07 for each additional unit of body mass index (Renehan et al, 2008). The increased prevalence of obesity likely contributes to the increased incidence of RCC in Western countries, and it has been estimated that more than 40% of cases of RCC in the United States may be causally linked to obesity (Calle and Kaaks, 2004). Potential mechanisms linking obesity to RCC include increased insulin-like growth factor-1 expression, increased circulating estrogen levels, and increased arteriolar nephrosclerosis and local inflammation (Calle and Kaaks, 2004; Ljungberg et al, 2011).

Hypertension appears to be the third major etiologic factor for RCC. Diuretics and other antihypertensive medications have also been implicated, but the weight of the epidemiologic evidence suggests that it is the underlying disorder, hypertension, rather than the treatment, that increases the risk of RCC (Lipworth et al, 2006; Ljungberg et al, 2011). The proposed mechanisms are hypertension-induced renal injury and inflammation or metabolic or functional changes in the renal tubules that may increase susceptibility to carcinogens (Lipworth et al, 2006; Ljungberg et al, 2011).

Although a number of other potential etiologic factors have been identified in animal models, including viruses, lead compounds, and more than 100 chemicals such as aromatic hydrocarbons, no specific agent has been definitively established as causative in human RCC. The potential role of trichloroethylene exposure has been actively investigated; some studies showed relative risks ranging from twofold to sixfold, but others have argued that inherent biases likely account for these results (Kelsh et al, 2010). Slightly increased relative risks for RCC have been reported for workers in the metal, chemical, rubber, and printing industries and those exposed to asbestos or cadmium, but the data are not particularly convincing (Ljungberg et al, 2011).

Case-control studies have shown that RCC is more common among individuals with low socioeconomic status and urban background, although the causative factors have not been defined. The typical modern Western diet (high in fat and protein), increased intake of dairy products, and increased consumption of coffee or tea have been associated with RCC, but the relative risks have been modest, and conflicting data are available in most instances (Ljungberg et al, 2011). A family history of RCC may also be a factor; one study showed a relative risk of 2.9 for individuals with a first- or second-degree relative with RCC (Gago-Dominguez et al, 2001).

Other potential iatrogenic causes include regular usage of non-steroidal anti-inflammatory drugs, which was associated with a relative risk of 1.51, while aspirin and acetaminophen were not associated with any increased risk (Cho et al, 2011). Retroperitoneal radiation therapy, typically administered for Wilms tumor or testicular cancer, appears to be a risk factor for RCC, although the relative risks are low (Romanenko et al, 2000). An increased incidence of RCC is also observed in patients with end-stage renal disease and certain familial syndromes such as tuberous sclerosis, as discussed later (Linehan and Ricketts, 2013).

Familial Renal Cell Carcinoma and Molecular Genetics

Since the early 1990s, significant advances have been made in our understanding of the molecular genetics of RCC. Novel familial syndromes of RCC have been identified, and the tumor suppressor genes and oncogenes contributing to the development of both sporadic and familial forms of this malignancy have been characterized (Table 57-2) (Linehan and Ricketts, 2013). The impact of this new information should not be underestimated because it has fundamentally changed our perceptions about RCC. We now, more than ever, recognize the distinct nature of the various subtypes of RCC, and advances in molecular genetics have contributed to a major revision in the histologic classification of this malignant neoplasm (Zhou, 2009; Linehan and Ricketts, 2013). A direct and beneficial impact on patient management has also been achieved,

with targeted molecular agents now extending survival for patients with advanced RCC (Linehan, 2012).

Knudson and Strong recognized that familial forms of cancer might hold the key to the identification of important regulatory elements known as tumor suppressor genes (Knudson, 1971; Knudson and Strong, 1972). Their observations about the childhood tumor retinoblastoma, in which familial cases tend to be multifocal and early onset, led them to propose a two-hit theory of carcinogenesis. They hypothesized that a gene product that could suppress tumor development must be involved and that both alleles of this “tumor suppressor gene” must be mutated or inactivated for tumorigenesis to occur. Furthermore, Knudson postulated that patients with familial cancers are born with one mutant allele and that all cells in that organ or tissue are at risk, accounting for the early onset and multifocal nature of the disease. In contrast, sporadic tumors develop only if a mutation occurs in both alleles within the same cell; and because each event occurs with low frequency, most tumors develop late in life and in a unifocal manner (Knudson, 1971; Knudson and Strong, 1972). Knudson’s hypothesis has proved true for retinoblastoma and a number of other tumor types, including RCC (Linehan and Ricketts, 2013). Identification of familial cases of RCC was particularly important because it allowed linkage analysis between affected family members.

von Hippel-Lindau Disease, VHL Gene, and Genetics of Clear Cell RCC

The familial form of clear cell RCC is von Hippel-Lindau disease. This is a relatively rare autosomal dominant disorder that occurs with a frequency of 1 per 36,000 population. Major manifestations include the development of RCC, pheochromocytoma, retinal angiomas, and hemangioblastomas of the brainstem, cerebellum, or spinal cord (Table 57-3) (Kim et al, 2010; Linehan and Ricketts, 2013). All of these tumor types are highly vascular and can lead to substantial morbidity, much of which can be avoided with prompt recognition and careful, skilled management. In particular, central nervous system lesions can lead to paralysis or death and retinal lesions to blindness if they are not identified and managed in an expedient manner. Other common or important manifestations of von Hippel-Lindau disease include renal and pancreatic cysts, inner ear tumors, and papillary cystadenomas of the epididymis (Neumann and Zbar, 1997). An increased incidence of neuroendocrine tumors of the pancreas has also been reported in von Hippel-Lindau disease (Zbar et al, 1999). Penetrance for all of these traits is far from complete, and some, such as pheochromocytomas, tend to be clustered only in certain families (Table 57-4) (Neumann and Zbar, 1997). RCC develops in about 50% of patients with von Hippel-Lindau disease and is distinctive for early age at onset (often in the third, fourth, or fifth decade of life) and bilateral and multifocal involvement (Kim et al, 2010; Linehan and Ricketts, 2013). With improved management of the central nervous system manifestations of the disease, RCC has now become the most common cause of mortality in patients with von Hippel-Lindau disease. Screening for von Hippel-Lindau disease and important considerations for the management of RCC in von Hippel-Lindau disease are reviewed later in this chapter.

Early clues to the genetic elements involved in RCC development came from cytogenetics. These studies demonstrated a common loss of chromosome 3 in kidney cancer, particularly the clear cell variant, and led to intensive efforts to find a tumor suppressor gene in this region (Zbar et al, 1987; Seizinger et al, 1988). Reports by Kovacs and colleagues (1989a) and Cohen and colleagues (1979) of translocations involving chromosome 3 further implicated this chromosome as an important regulatory element. Sophisticated molecular genetic linkage studies in patients with von Hippel-Lindau disease eventually led to the identification of the VHL tumor suppressor gene (Latif et al, 1993). The role of this gene at chromosome 3p25-26 as a tumor suppressor for both sporadic and familial forms of clear cell RCC has been confirmed (Linehan

TABLE 57-2 Familial Renal Cell Carcinoma (RCC) Subtypes

SUBTYPE	GENE (CHROMOSOME)	MAJOR CLINICAL MANIFESTATIONS
von Hippel-Lindau disease	<i>VHL</i> gene (3p25-26)	Clear cell RCC Retinal angiomas Central nervous system hemangioblastomas Pheochromocytoma Other tumors
Hereditary papillary RCC	<i>c-MET</i> proto-oncogene (7q31)	Multiple, bilateral type 1 papillary RCCs
Familial leiomyomatosis and RCC	Fumarate hydratase (1q42-43)	Type 2 papillary RCC Collecting duct carcinoma Leiomyomas of skin or uterus Uterine leiomyosarcomas
Birt-Hogg-Dubé syndrome	Folliculin (17p11)	Multiple chromophobe RCC, hybrid oncocyctic tumor, oncocytomas Clear cell RCC (occasionally) Papillary RCC (occasionally) Facial fibrofolliculomas Lung cysts Spontaneous pneumothorax
Succinate dehydrogenase RCC	Succinate dehydrogenase complex subunits: <i>SDHB</i> (1p36.1-35) or <i>SDHD</i> (11q23)	Chromophobe, clear cell, type 2 papillary RCC; oncocytoma Paragangliomas (benign and malignant) Papillary thyroid carcinoma
Tuberous sclerosis	<i>TSC1</i> (9q34) or <i>TSC2</i> (16p13)	Multiple renal angiomyolipomas Clear cell RCC (occasionally) Renal cysts/polycystic kidney disease Cutaneous angiofibromas Pulmonary lymphangioleiomyomatosis
PTEN hamartoma tumor syndrome (Cowden syndrome)	<i>PTEN</i> (10q23)	Breast tumors (malignant and benign) Epithelial thyroid carcinoma Papillary RCC or other histology

Third International Meeting on von Hippel-Lindau disease. *Cancer Res* 1999;59:2251-3; and Linehan WM, Ricketts CJ. The metabolic basis of kidney cancer. *Semin Cancer Biol* 2013;23:46-55.

and Ricketts, 2013). The *VHL* gene consists of three exons, and it encodes a protein of 213 amino acids. A large number of common mutations or “hot spots” in the gene have been identified, and a direct correlation between genotype and phenotype has been established in some cases (McNeill et al, 2009). For instance, missense mutations (type 2 mutations) that result in a full-length but non-functional protein are commonly found in families with von

Hippel-Lindau disease that develop pheochromocytomas, whereas deletions leading to a truncated protein (type 1 mutations) are typically found in families that do not develop pheochromocytomas (see Table 57-4) (McNeill et al, 2009). The identification of this tumor suppressor gene represented a major advance in the field and required close collaboration between clinical urologic oncologists and molecular geneticists. The important historical steps in solving

TABLE 57-4 Incidence of the Major Manifestations of von Hippel-Lindau Disease by Mutation Status

DISEASE TYPE	HEMANGIOBLASTOMA	RCC	PHEOCHROMOCYTOMA	GERMLINE MUTATION TYPES
1	High	High	Low	Full gene deletions, partial gene deletions, nonsense mutations, splice acceptor mutations
2A	High	Low	High	Missense mutations (surface mutations causing only partial loss of function)
2B	High	High	High	Partial gene deletions, nonsense mutations, missense mutations (in elongin C binding area)

Figure 57-7. Biologic functions of the von Hippel-Lindau (VHL) protein. The wild-type VHL protein targets hypoxia-inducible factor-2α (HIF-2α) for degradation. Mutation of the VHL gene allows HIF-2α to accumulate, leading to increased expression of vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), glucose transporter 1 (Glut 1), and transforming growth factor-α (TGF-α). This in turn has important implications with respect to tumor angiogenesis, metabolic activity, and autocrine and paracrine stimulation. RCC, renal cell carcinoma. (From Linehan WM, Walther MM, Zbar B. The genetic basis of cancer of the kidney. *J Urol* 2003;170:2163–72.)

this challenging puzzle have been reviewed by Linehan and Zbar and their colleagues, who spearheaded this important effort (Linehan and Ricketts, 2013).

Subsequent work has focused on the function of the VHL protein and its likely mechanisms of action. The VHL protein is known to bind to elongins B and C, CUL-2, and RBX1 to form an E3 ubiquitin ligase complex, and thereby modulates the degradation of important regulatory proteins (Linehan and Ricketts, 2013; Shen and Kaelin, 2013). A critically important function of the VHL protein complex is to target the hypoxia-inducible factors 1α and 2α (HIF-1α and HIF-2α) for ubiquitin-mediated degradation, keeping the levels of HIFs low under normal conditions. The HIFs are intracellular proteins that play an important role in regulating cellular responses to hypoxia, starvation, and other stresses. Inactivation or mutation of the VHL gene leads to

accumulation of HIFs, most notably HIF-2α (Shen and Kaelin, 2013). Accumulation of HIF-2α leads to a severalfold upregulation of the expression of vascular endothelial growth factor (VEGF), the primary angiogenic growth factor in RCC, contributing to the pronounced neovascularity associated with clear cell RCC. HIF-2α also upregulates the expression of transforming growth factor-α, platelet-derived growth factor, glucose transporter 1, erythropoietin, and carbonic anhydrase IX, which also promote tumorigenesis (Fig. 57-7). Through these and other mechanisms the VHL protein appears to influence the cell cycle, cellular differentiation, tumor invasiveness, intracellular processing of important matrix molecules, and immunomodulatory status (Shen and Kaelin, 2013). VHL also upregulates HIF-1α, which to some extent counterbalances the tumorigenic effects of HIF-2α, and this remains an important area of investigation (Shen and Kaelin, 2013).

The other three most commonly mutated genes involved in the development of sporadic clear cell RCC are also located on the short arm of chromosome 3, which is affected in more than 90% of clear cell RCC cases (Cancer Genome Atlas Research Network, 2013). Unlike *VHL*, these genes, which include *PBRM1*, *BAP1*, and *SETD2*, are all involved in chromatin remodeling and histone methylation (Dalglish et al, 2010; Varela et al, 2011; Cancer Genome Atlas Research Network, 2013; Farley et al, 2013). *SETD2* mutations, for instance, have been shown to result in alterations in methylation status at multiple sites of the genome (Varela et al, 2011).

Familial Papillary Renal Cell Carcinoma and Genetics of Papillary Renal Cell Carcinoma

Several studies have documented distinct cytogenetic findings in non-clear cell histiotypes of RCC; chromosome 3 and *VHL* gene abnormalities are uncommon in these variants (Linehan and Ricketts, 2013). These observations suggested a distinct genetic basis for non-clear cell RCC. Papillary RCC, the second most common histologic subtype of RCC, is characterized by trisomy for chromosomes 7 and 17 as well as abnormalities on chromosomes 1, 12, 16, 20, and Y (Linehan and Ricketts, 2013). In 1995, Zbar and colleagues at the National Cancer Institute reported a second familial syndrome of RCC—hereditary papillary RCC (HPRCC). This followed a number of isolated case reports that suggested clustering of papillary RCCs within certain families. In Zbar and colleagues' series (1995) there were 10 families with 41 affected members (29 men and 12 women). Median age at diagnosis was 45 years, and most patients developed multifocal and bilateral papillary RCC. Type 1 papillary RCC is typically found in this syndrome rather than type 2, which is commonly seen in the hereditary leiomyomatosis and RCC syndrome. Unlike von Hippel-Lindau disease, most patients with HPRCC do not develop tumors in other organ systems (Linehan and Ricketts, 2013). Mean survival in affected individuals was only 52 years in Zbar and colleagues' series, although the number of patients dying of RCC was not defined. The development of CKD as a result of a combination of malignant replacement of the renal mass and loss of functioning nephrons secondary to various interventions is a potential contributor to morbidity and mortality in this syndrome (Ornstein et al, 2000). CT is the preferred imaging modality for patients with HPRCC because it has the greatest sensitivity for detecting the small, hypovascular lesions that are common in this syndrome.

Studies of families with HPRCC demonstrate an autosomal dominant mode of transmission, similar to all of the familial RCC syndromes, and provide insight into the molecular genetics of HPRCC as well as a subset of patients with sporadic papillary RCC (Linehan and Ricketts, 2013). Again, molecular linkage analysis in affected families played a key role in the discovery of this gene, which was localized to chromosome 7q31. However, in this case, the inciting event is activation of a proto-oncogene, rather than inactivation of a tumor suppressor gene. Missense mutations of the *c-MET* proto-oncogene at 7q31 were found to segregate with the disease, implicating it as the relevant genetic locus (Schmidt et al, 1997). The protein product of this gene is the receptor tyrosine kinase for hepatocyte growth factor, also known as scatter factor, and its activation leads to cellular proliferation and other potential tumorigenic effects (Vira et al, 2007). Most of the mutations in HPRCC have been found in the tyrosine kinase domain of *c-MET* and apparently lead to constitutive activation (Schmidt et al, 1997; Sudarshan and Linehan, 2006). Relatively early onset and multifocality in HPRCC are due to inheritance of the mutated *c-MET* gene, which places all the cells in the kidney at risk from birth, but the incomplete penetrance and variable clinical course associated with this syndrome suggest that additional genetic loci or epigenetic phenomena may modulate the phenotype (Linehan and Ricketts, 2013). Whereas tumors in HPRCC tend to be less aggressive than their sporadic counterparts, it is clear that some can metastasize and become lethal. Schmidt and colleagues reported *c-MET* mutations in 13% of

patients with sporadic papillary RCC, suggesting that this molecular defect also contributes to a subset of this disease population (Sudarshan and Linehan, 2006; Linehan and Ricketts, 2013). Small molecule inhibitors of the *c-MET* receptor are currently in development and may prove useful for the management of HPRCC and the subset of patients with sporadic RCC who harbor this mutation (Bellon et al, 2008; Pfaffenroth and Linehan, 2008; Linehan and Ricketts, 2013).

Hereditary Leiomyomatosis and Renal Cell Carcinoma

In 2001, Launonen and colleagues described a new familial renal cancer syndrome in which patients commonly develop cutaneous and uterine leiomyomas and type 2 papillary RCC (Linehan and Ricketts, 2013). Mean age at diagnosis is in the early 40s. Renal tumors in this syndrome are unusual for familial RCC in that they are often solitary and unilateral, and they are more likely to be aggressive than other forms of familial RCC. Collecting duct carcinoma, another highly malignant variant of RCC, has also been observed in this syndrome, which was named hereditary leiomyomatosis and renal cell carcinoma (HLRCC) syndrome.

The HLRCC locus was mapped to a region on 1q42-44, and this was later shown to be the site of the fumarate hydratase gene (Tomlinson et al, 2002; Toro et al, 2003; Alam et al, 2005; Pavlovich et al, 2005). Again, autosomal dominant inheritance was observed, and this appears to be a tumor suppressor gene rather than an oncogene. Fumarate hydratase is an essential enzyme in the Krebs cycle of oxidative metabolism. The exact mechanisms by which this leads to malignancy are still under investigation, although hypotheses about this date back to the 1920s and the proposed Warburg effect. One potential explanation is that inactivation of mitochondrial oxidative metabolism prevents the cell from efficiently creating ATP from glucose, leaving the cell with the sense that it is in an anaerobic or hypoxic environment. This in turn may lead to increased expression of growth factors and thus promote tumorigenesis.

Penetrance for RCC in HLRCC is lower than for the cutaneous and uterine manifestations, with only a minority (20%) of patients developing RCC. In contrast, almost all individuals with this syndrome will develop cutaneous leiomyomas and uterine fibroids (if female), usually manifesting at the age of 20 to 35 years. A high proportion of women have had a hysterectomy for fibroids before formal diagnosis of HLRCC (Coleman, 2008). Leiomyosarcomas of the uterus have been reported in HLRCC, although they appear to be uncommon (Sudarshan and Linehan, 2006; Pfaffenroth and Linehan, 2008). Prompt surgical management of the renal tumors is recommended in this syndrome, given their tendency toward aggressive behavior (Grubb et al, 2007; Coleman, 2008). This is in contrast to most of the other familial syndromes of RCC, for which management tends to be more conservative.

Succinate Dehydrogenase Renal Cell Carcinoma

A newly described familial RCC syndrome that shares many features with HLRCC is succinate dehydrogenase renal cell carcinoma (SDH-RCC) (Ricketts et al, 2012). Individuals with germline mutation of one of the multiple genes encoding subunits of the Krebs cycle enzyme succinate dehydrogenase, including *SDHB*, *SDHC*, and *SDHD*, are at increased risk for RCC, which can also follow an aggressive clinical course (Vanharanta et al, 2004; Ricketts et al, 2008, 2012). Another example of the Warburg effect in cancer, individuals with SDH-RCC typically present with early onset and aggressive disease, leading Linehan and colleagues to recommend wide surgical excision of these tumors when suspected (Ricketts et al, 2012).

Birt-Hogg-Dubé Syndrome

Birt-Hogg-Dubé syndrome, in which patients develop cutaneous fibrofolliculomas, lung cysts, spontaneous pneumothoraces, and

a variety of renal tumors primarily derived from the distal nephron, is named after three Canadian physicians who first described the cutaneous lesions in 1977 (Pavlovich et al, 2005; Adley et al, 2006). The renal tumors typically include chromophobe RCC, oncocytomas, and hybrid or transitional tumors that exhibit features of both of these entities (Boris et al, 2011). However, other forms of RCC, including a substantial proportion of clear cell RCC, have been observed in this syndrome (Adley et al, 2006). Overall penetrance for renal tumors is 20% to 40%, but when they occur they are often bilateral and multifocal (Pavlovich et al, 2005; Toro et al, 2008). Average age at renal tumor diagnosis is approximately 50 years. Most renal tumors in Birt-Hogg-Dubé syndrome have limited biologic aggressiveness, although metastatic behavior and lethality have been reported (Pavlovich et al, 2005).

The *BHD* gene responsible for this syndrome has been mapped to chromosome 17p12q11.2 and is now fully sequenced (Khoo et al, 2001). Recent studies have shown that the gene product is the tumor suppressor folliculin (Adley et al, 2006; Toro et al, 2008). Folliculin forms a complex of proteins that appears to interface with the mammalian target of rapamycin (mTOR) pathway, and germline mutations in this gene have been found in 88% of kindreds (Toro et al, 2008). When folliculin is inactivated, both mTOR signaling complexes 1 and 2 (mTORC1 and mTORC2) are activated, which leads to increased transcriptional activity and nuclear translocation of TFE3 (Hasumi et al, 2009; Hong et al, 2010). As with all of the other well-characterized familial RCC syndromes, an autosomal dominant pattern of inheritance is observed and genetic testing is now available (see Table 57-2).

Cowden Syndrome

Cowden syndrome is one of several syndromes that result from germline mutations of the phosphatase and tensin homolog (*PTEN*) tumor suppressor gene, which together are termed *PTEN* hamartoma tumor syndrome. Individuals with Cowden syndrome carry a 50% lifetime risk of female breast cancer, 34% lifetime risk of RCC, and 10% lifetime risk of epithelial thyroid carcinoma (Starink et al, 1986; Mester et al, 2012). Patients with clinical features of Cowden syndrome but without *PTEN* mutations were subsequently found to have mutations in *KILLIN*, an adjacent tumor suppressor gene that was also associated with increased incidence of RCC (Bennett et al, 2010). Based on a greater than 31-fold increased risk of RCC, individuals with Cowden or Cowden-like syndrome should be screened with CT or MRI for RCC. RCC in this syndrome is most often of papillary histology, although chromophobe and clear cell histology have also been reported (Mester et al, 2012; Shuch et al, 2013b).

Tumor Biology and Clinical Implications

Resistance to Cytotoxic Therapy

RCC is a prototype of the chemorefractory tumor because it has demonstrated only limited or modest responses to traditional chemotherapeutics (Motzer and Russo, 2000; Rini et al, 2009). Study of the tumor biology of RCC provides insight into its refractory nature and, through elucidation of the VEGF and mTOR pathways, has yielded agents with clinical benefit for advanced disease (Table 57-5) (Rini et al, 2009). Expression of multidrug resistance proteins, which act as energy-dependent efflux pumps for a wide variety of hydrophobic compounds, contributes to the chemorefractory nature of advanced RCC. However, the resistance of RCC to cisplatin and other agents that are not extruded by multidrug resistance proteins suggests redundancy in resistance mechanisms. The ancillary benefit of this refractoriness has been an impetus for clinical investigations of immunomodulators and targeted molecular therapies, which have markedly altered our paradigms for the management of patients with advanced RCC (see Chapter 63).

TABLE 57-5 Tumor Biology and Clinical Implications

BIOLOGIC CHARACTERISTIC	CLINICAL IMPLICATIONS
Expression of multidrug resistance	Contributes to chemorefractory nature of RCC
Immunogenic	10%-20% response rate with interferon or IL-2 3%-5% complete response rate with high-dose IL-2 Modulation of PD-1 and other costimulatory molecules is under active investigation
Angiogenic	Vascular invasion can lead to venous tumor thrombus 20%-40% response rates with agents targeting VEGF (bevacizumab) or the VEGF receptor (sunitinib, sorafenib, pazopanib, axitinib, etc.) Prolonged recurrence-free survival and overall survival with some antiangiogenic agents
Dependence on mTOR pathway	Agents targeting mTOR prolong survival in patients with poor-risk RCC (temsirolimus) and demonstrate responses in patients failing prior targeted molecular therapies (everolimus)

IL-2, interleukin-2; mTOR, mammalian target of rapamycin; PD-1, programmed death-1; RCC, renal cell carcinoma; VEGF, vascular endothelial growth factor.

Immunobiology and Immune Tolerance

Several lines of evidence demonstrate that RCC is immunogenic, and this knowledge has stimulated intensive efforts to harness the immune system to improve outcomes for patients with advanced disease (McDermott and Atkins, 2013). Tumor-infiltrating immune cells can be readily isolated from RCC, including cytotoxic T cells with specificity for antigens on tumor cells as well as dendritic cells and helper T cells, which express interleukin (IL)-1 and IL-2 and function as antigen-presenting cells. The molecular mechanisms involved in the interactions of the host immune system with the tumor have yielded insights and promising new therapies for RCC (McDermott and Atkins, 2013). New agents that activate or block downregulation of T cells, prime dendritic cells with tumor antigens, or inhibit tumor-induced immunosuppression have entered clinical trials (Brahmer et al, 2012).

Of the tumor-associated antigens for RCC, carbonic anhydrase IX (CA-IX or MN-9) has demonstrated the most specificity (Shuch et al, 2008). This antigen, which is recognized by the G250 monoclonal antibody, is expressed almost ubiquitously by clear cell RCC and only rarely by other RCC subtypes. Immunohistochemical analysis of CA-IX expression has been investigated as a diagnostic and a prognostic marker for clear cell RCC (Bui et al, 2003; Divgi et al, 2007, 2013; Leibovich et al, 2007). In normal tissues, the expression of CA-IX is restricted to the gastric mucosa, large bile ducts, and pancreas, and its expression in normal renal epithelial cells is suppressed by wild-type VHL protein. Radioactively labeled G250 has shown promise for the detection of RCC metastases by radionuclide scanning (Brouwers et al, 2003), and more recently by positron emission tomography (Divgi et al, 2007, 2013). All these potential applications of CA-IX are, at present, promising but experimental.

A second class of factors that may modulate immunotherapeutic responses in kidney cancer are factors that downregulate

effector T cells (McDermott and Atkins, 2013). Cytotoxic T-lymphocyte antigen-4 (CTLA-4) expression on the surface of activated T cells halts the immune response to the tumor. Blockade of CTLA-4, such as by the CTLA-4 antibody ipilimumab, leads to major tumor responses, but also significant potential toxicity. Similarly, the programmed death-1 (PD-1) and programmed death ligand-1 (PD-L1) pathway leads to decreased effector T-cell activity. PD-L1 (or B7-H1) is a member of a family of cell surface glycoproteins that are expressed on various immune and nonimmune cells (Thompson et al, 2007b). PD-L1 is a T-cell coregulatory molecule that is normally expressed by macrophage lineage cells, can be induced on activated T lymphocytes, and is aberrantly expressed by RCC (Thompson et al, 2007b). Tumor-associated PD-L1 impairs antigen-specific T-cell function, and blockade of this pathway has been shown to potentiate antitumoral responses in preclinical models (Thompson et al, 2004). Thompson and associates (2006) have shown that PD-L1 expression by clear cell RCC tumors correlates with aggressive pathologic features and is associated with an increased risk of disease progression, even after multivariate adjustment. PD-1 blockade has been associated with significant clinical response in phase I and II trials, and phase III testing is ongoing at present (McDermott and Atkins, 2013).

Clinical observations such as validated responses to immunotherapy, prolonged disease stabilization, and occasional spontaneous tumor regression also support the immunogenicity of RCC. The response of RCC to immunomodulators, such as IL-2, interferon- α , and tumor-infiltrating lymphocytes, argues in favor of an important role for the immune system in the tumor biology of RCC (Coppin, 2008). Indeed, high-dose IL-2 remains a treatment with curative potential for patients with metastatic RCC, with durable and complete regression of disease accomplished in a finite proportion (3% to 5%) of patients (Coppin, 2008; Amin and White, 2013). The estimated incidence of spontaneous regression of RCC is between 0.3% and 1% (Oliver et al, 1989). Most spontaneous regressions have been noted in patients with pulmonary metastases and have occurred after cytoreductive nephrectomy, but regression of primary RCC has also been reported in the absence of any form of treatment (Vogelzang et al, 1992). Remission can be durable, and this phenomenon, although rare, is thought to be real and has been assumed to be due to immune surveillance, although other possibilities cannot be excluded (Coppin, 2008).

Unfortunately, response rates of immunotherapy for RCC have been disappointing, typically ranging from 15% to 20%, despite a variety of creative treatment strategies, suggesting immune tolerance (Amin and White, 2013). A number of observations support impaired immune surveillance in RCC, and a variety of mechanisms affecting virtually all levels of regulation of the immune system have been proposed. Defects in transcriptional regulation via nuclear factor- κ B are present in the tumor-infiltrating lymphocytes and dendritic cells of 60% of RCCs (Finke et al, 2001; Thornton et al, 2004). Defective nuclear factor- κ B signaling impairs lymphocyte function, predisposes lymphocytes to apoptosis, and leads to deficient recruitment and activation of dendritic cells. Improved understanding of the mechanisms contributing to immunotolerance in RCC should suggest novel and rational strategies for improving outcomes for patients with advanced disease. For example, in addition to its anti-VEGF activity, sunitinib also appears to stimulate antitumor immunity by reversing myeloid-derived suppressor cell-mediated immunosuppression (Ko et al, 2009).

Angiogenesis and Targeted Pathways

RCC has long been recognized as one of the most vascular of cancers, as reflected by the distinctive neovascular pattern exhibited on renal angiography and robust enhancement observed on dedicated renal CT. The primary angiogenesis inducer in clear cell RCC is VEGF, which is suppressed by the wild-type VHL protein under normal conditions and is dramatically upregulated during tumor development (Gnarra et al, 1996; Iliopoulos

et al, 1996). Functional relevance of VEGF has been demonstrated by studies showing increased levels of VEGF in the serum and urine of patients with RCC. Increased expression of VEGF is also found in hypervascular tumors when compared to hypovascular tumors (Takahashi et al, 1994).

VEGF is actually a family of ligands consisting of several subtypes, most of which are regulated by HIFs and VHL and bind to one or more of the corresponding VEGF receptor (VEGFR) family members (Lane et al, 2007c). VEGFR-1 (Flt-1) and VEGFR-2 (KDR/Flk-1) are receptor tyrosine kinases that are the target of several multi-tyrosine kinase inhibitors with activity against RCC (Carmeliet, 2005; Hicklin and Ellis, 2005). Upon binding of ligand (VEGF), key tyrosine residues along the intracellular portion of the VEGFR are phosphorylated, which leads to the binding of specific intracellular factors and activation of corresponding signal transduction pathways. Pathways known to be activated by phosphorylation of VEGFRs include the Raf-MEK-Erk and phosphatidylinositol-3-kinase/Akt/mTOR pathways that promote endothelial cell survival and proliferation (Carmeliet, 2005; Hicklin and Ellis, 2005). However, the promiscuity of the interactions between the various ligands, receptors, and downstream effectors leads to a variety of effects that may be difficult to predict in the absence of analyses investigating the complete microenvironment of the cancer or endothelial cell. This promiscuity is likely a major reason that therapeutic agents that have similar modes of action (so-called VEGF receptor tyrosine kinase inhibitors) are found to have somewhat disparate clinical or off-target effects. In contrast, bevacizumab is a monoclonal antibody that binds to VEGF and sequesters the ligand so that it cannot interact with VEGFR; its clinical activity is therefore almost certainly directly related to this activity.

Given the dependence of RCC on angiogenesis and the absence of generally effective forms of systemic therapies in the previous millennium, it is not surprising that RCC has been targeted for anti-VEGF approaches. Initial clinical trials identified several antiangiogenic compounds, such as TNP-470, roquinoximex, and thalidomide, with limited activity in patients with advanced RCC (de Wit et al, 1997; Stadler et al, 1999). More promising results were then reported for bevacizumab, a humanized anti-VEGF antibody that was associated with a significant delay in time to progression for patients with metastatic RCC compared with placebo (Yang et al, 2003). Bevacizumab therapy commonly leads to shrinkage in the total tumor burden, although in this initial experience objective partial responses were uncommon and there were no complete responses, consistent with a tumorostatic rather than a tumoricidal mechanism of action. A number of other multiple kinase inhibitors that target the VEGF pathway were subsequently tested in clinical trials and found to have substantial activity in patients with advanced RCC, culminating in approval of several such agents by the U.S. Food and Drug Administration (FDA) beginning in December 2005 and extending into the current era (see further details in Chapter 63) (Motzer et al, 2006, 2013a, 2013b; Haddad and Rini, 2012).

More recently, the Cancer Genome Atlas Research Network (2013) has provided a comprehensive molecular characterization of clear cell RCC that will serve as a solid foundation for future studies in this field. Analyses performed in this landmark study included next-generation sequencing to evaluate the whole genome of 22 tumors and whole-exome sequencing of 417 additional tumors. DNA copy number and genotype, CpG DNA methylation, messenger RNA expression, microRNA expression, and protein expression were also analyzed in these same 400-plus tumors, providing a wealth of information about the molecular features of clear cell RCC. Main findings included the identification of alterations in genes controlling cellular oxygen sensing, such as VHL, and the maintenance of chromatin states, such as PBRM1, BAP1, and SETD2. In total, 19 significantly mutated genes were identified, including the above but also genes involved in the PI3K/AKT pathway (Dalgleish et al, 2010). Mutation of the H3K36 methyltransferase SETD2 was notable in that it is associated with widespread DNA hypomethylation, and complex integrative analyses suggested that mutations involving the SWI/SNF chromatin

remodeling complex (*PBRM1*, *ARID1A*, *SMARCA4*) could have broad effects on other signaling pathways. Overall, the analyses provided strong evidence for a metabolic shift in aggressive cancers, with downregulation of genes involved in the tricarboxylic acid (TCA) cycle, upregulation of pentose phosphate and glutamine transporter genes, decreased AMPK and PTEN protein levels, and increased acetyl coenzyme A carboxylase protein. **The recurring theme of metabolic remodeling in clear cell RCC suggests multiple new windows into future targets for disease treatment.**

Other Signal Transduction and Cell Cycle Regulation Pathways

Aberrant activation of additional signal transduction pathways in RCC may also contribute to altered cell cycle kinetics, and these pathways represent excellent targets for therapeutic

intervention. One such regulatory pathway in RCC is the mTOR pathway, which interfaces with Akt (protein kinase B) and the *PTEN* tumor suppressor gene (Hudes, 2009; Barthélémy et al, 2013). Expression of mTOR is upregulated by various growth factors or by mutation or loss of *PTEN*. Through complex pathways involving a variety of intermediaries, the mTOR pathway leads to increased expression of HIF-1 and other growth-promoting and potentially tumorigenic sequelae. Inhibition of mTOR with temsirolimus (Torisel) has yielded prolonged survival in patients with poor-risk, metastatic RCC, and everolimus (Afinitor) has shown efficacy for patients who have failed tyrosine kinase inhibitors, confirming the clinical relevance of the mTOR pathway (Hudes et al, 2007; Motzer et al, 2008). Both of these mTOR inhibitors are now also approved by the FDA. Other potential factors involved in RCC pathogenesis, including the *c-MET* proto-oncogene, the insulin-like growth factor axis, telomerase, apoptotic factors, and extracellular matrix proteins, are reviewed in Box 57-3.

BOX 57-3 Tumor Biology: Other Signal Transduction and Cell Cycle Regulation Pathways

A wide array of cellular factors has been shown to be dysregulated in the serum, urine, and/or tumors of patients with RCC. None of these associations, however, has been sufficiently validated to be used in routine clinical practice. For example, increased telomerase activity, which has been found in 56% to 93% of RCCs, may affect the cell cycle by maintaining telomere length (Mehle et al, 1994; Yoshida et al, 1998). Progressive telomere loss occurs each time a normal cell divides and eventually leads to growth inhibition and cellular senescence (Mekhail et al, 2003). Dysregulation of factors involved in apoptosis, or programmed cell death, has also been reported in RCC and may contribute to tumor viability and treatment failure (Gobé et al, 2002; Rajandram et al, 2012; Sejima et al, 2012). Insulin-like growth factor receptor expression has also been correlated with decreased survival in patients with RCC (Parker et al, 2003a).

Proliferative index, as defined by proliferating cell nuclear antigen or Ki-67 staining, has correlated with pathologic parameters and clinical outcomes in RCC, suggesting that regulation of the cell cycle plays an important role in the tumor biology of RCC (Bui et al, 2004; Tollefson et al, 2007). **Increased expression of transforming growth factor- α and its receptor tyrosine kinase, the epidermal growth factor receptor (EGFR), have been reported in RCC** and may contribute to tumorigenesis by promoting cell proliferation or transformation through an autocrine mechanism. The functional relevance of EGFR in the development of RCC has also been suggested by preclinical studies testing the efficacy of the C225 monoclonal antibody, which neutralizes EGFR and blocks tumor growth and metastasis. Unfortunately, phase II clinical trials using agents that target EGFR, including erlotinib (Tarceva), gefitinib (Iressa), panitumumab (Vectibix), and lapatinib (Tykerb), demonstrated a lack of substantial activity in patients with advanced RCC (Rini, 2010). Based on these disappointing results, agents targeting the EGFR pathway have fallen out of favor, although selective treatment of patients who overexpress EGFR may still be a consideration in the future.

The hepatocyte growth factor and its receptor, the *c-MET* proto-oncogene, may also contribute to the pathogenesis of RCC (Giubellino et al, 2009; Gibney et al, 2013; Harshman and Choueiri, 2013). The role of activating mutations of the *c-MET* proto-oncogene in the etiology of hereditary papillary RCC has already been discussed, but data suggest that upregulated expression of this ligand may occur in most of the histologic subtypes of RCC (Giubellino et al, 2009; Harshman and Choueiri, 2013). Hepatocyte

growth factor is expressed by proximal tubular cells in the normal kidney, where it is involved in branching tubulogenesis of the developing kidney and regeneration after renal injury. In vitro, hepatocyte growth factor has mitogenic and morphogenic effects on renal epithelial cells. Increased serum levels of hepatocyte growth factor have also been reported in most patients with RCC, independent of histologic subtype, and activation of the receptor by phosphorylation at two sites is associated with cancer progression, making *c-Met* a potential therapeutic target for RCC (Gibney et al, 2013). Taken together, these data suggest that hepatocyte growth factor and its receptor may play an important role in the tumor biology of RCC, although constitutive activation of the receptor, which may be the most potent mechanism, appears to be primarily limited to familial papillary RCC.

PROTEASES, ADHESION, AND THE EXTRACELLULAR MATRIX

Interactions among cancer cells, adjacent cells, and the surrounding matrix can strongly influence their pathogenic potential (Jonasch et al, 2012). Altered intracellular processing and secretion of fibronectin and other matrix proteins is found in RCC, representing one consequence of *VHL* gene mutation (Ohh et al, 1998). This fundamental defect most likely has important effects on tumor biology, given the important role of the matrix in regulating cellular differentiation and tumor invasiveness and metastasis. Increased expression of proteases, such as plasmin and the matrix metalloproteinases, has correlated with reduced survival in RCC and may also contribute to the aggressive behavior of RCC (Jonasch et al, 2012). Downregulation of E-cadherin and cadherin-6, which mediate adhesion between cancer cells, is well documented in RCC and has correlated with poor outcomes in most studies (Russell and Ohh, 2007). Aberrant regulation of the catenin family, the cytoplasmic proteins that bind cadherins and mediate their effects on the cytoskeleton, has also been observed in RCC, and a correlation with compromised survival has been reported (Banumathy and Cairns, 2010).

Other studies have defined the adhesion molecules that facilitate interactions between tumor cells and endothelial cells in RCC (Banumathy and Cairns, 2010). Sialyl-Lewis^x/endothelial leukocyte adhesion molecule-1 and very late antigen-4/vascular cell adhesion molecule-1 interactions regulate this process, which presumably influences the ability of tumor cells to move into or out of the vascular system during the metastatic cascade (Steinbach et al, 1996; Ohba et al, 2005).

Pathology

Most RCCs are round to ovoid and circumscribed by a pseudo-capsule of compressed parenchyma and fibrous tissue rather than a true histologic capsule. Unlike upper tract urothelial carcinomas, most RCCs are not grossly infiltrative, with the notable exception of collecting duct carcinoma and sarcomatoid variants. Tumor size has averaged between 4 and 8 cm in most series but can vary from a few millimeters to large enough to fill the entire abdomen. Tumors smaller than 3 cm were previously classified as benign adenomas, but some small tumors have been associated with metastases (Nguyen and Gill, 2009), and most pathologists agree that, with the exception of oncocytomas and some small (<5-mm) low-grade papillary adenomas, there are no reliable histologic or ultrastructural criteria to differentiate benign from malignant renal epithelial tumors (see Chapter 56). When they are bivalved, RCCs consist of yellow, tan, or brown tumor interspersed with fibrotic, necrotic, or hemorrhagic areas; few are uniform in gross appearance. Cystic degeneration is found in 10% to 25% of RCCs and appears to be associated with a better prognosis compared with purely solid RCC (Webster et al, 2007; Jhaveri et al, 2013). Calcification can be stippled or plaquelike and is found in 10% to 20% of RCCs.

Nuclear features can be highly variable. Grading has been based primarily on nuclear size and shape and the presence or absence of prominent nucleoli. Fuhrman’s system (Table 57-6) is an independent prognostic factor for RCC generally and for clear cell RCC in particular (Fuhrman et al, 1982). Recent evidence suggests that Fuhrman grade is also a significant predictor of outcome for papillary RCC (Klatte et al, 2010a; Sukov et al, 2012), but features other than nuclear characteristics may form the basis of a preferred scheme for chromophobe RCC (Delahunt et al, 2007; Finley et al, 2011; Cheville et al, 2012).

Aggressive local behavior is not uncommon with RCC and can be expressed in a variety of ways. Frank invasion and perforation of the renal capsule, renal sinus, or collecting system are found in approximately 20% of cases, although displacement of these structures is a more common finding. Further spread to involve adjacent organs or the abdominal wall is often precluded by the Gerota fascia, although some high-grade RCCs are able to overcome this natural barrier. One unique feature of RCC is its predilection for involvement of the venous system, which is found in 10% of RCCs, more often than in any other tumor type (Skinner et al, 1972; Scheff et al, 1978). This is most commonly manifested in the form of a contiguous tumor thrombus that can extend into the inferior vena cava (IVC) as high as the right atrium. Many such tumor thrombi are highly vascularized by arterial blood flow (Novick et al, 1990), and some directly invade the wall of the renal vein or vena cava, which correlates with compromised prognosis (Skinner et al, 1972; Scheff et al, 1978; Zini et al, 2008).

Most sporadic RCCs are unilateral and unifocal. Bilateral involvement can be synchronous or asynchronous and is found in 2% to 4% of sporadic RCCs, although it is considerably more common in patients with familial forms of RCC, such as von Hippel-Lindau disease. Multicentricity, which is found in 10% to 20% of cases, is more common in association with papillary histology and familial RCC (Mukamel et al, 1988; Cheng et al, 1991; Krambeck et al, 2008). Satellite lesions are often small and

difficult to identify by preoperative imaging, intraoperative ultrasonography, or visual inspection; they appear to be the main factor contributing to local recurrence after partial nephrectomy (Mukamel et al, 1988). Microsatellite analysis suggests a clonal origin for most multifocal RCC within the same kidney (Junker et al, 2002), but tumor in the contralateral kidney is likely to be an independent growth if it is synchronous or a metastasis if it is asynchronous (Kito et al, 2002). Molecular analyses, such as gene expression profiling, may help to determine whether an asynchronous tumor is a second primary tumor or a metastasis (Lane et al, 2009a). Most recently, comprehensive sequencing of multiple biopsy specimens obtained from primary and metastatic tumors in the same patient has revealed significant intratumor heterogeneity (Gerlinger et al, 2012). These studies suggest that analysis of single biopsy samples may underestimate this inherent heterogeneity and prevent discernment of “driver” mutations from “passenger” mutations, presenting significant challenges to personalized medicine and biomarker development.

All RCCs are, by definition, adenocarcinomas, derived from renal tubular epithelial cells (Zhou, 2009) (Table 57-7). Most RCCs share ultrastructural features, such as surface microvilli and complex intracellular junctions, with normal proximal tubular cells and are believed to be derived from this region of the nephron (Kim and Kim, 2002; Axelson and Johansson, 2013). Two aggressive subtypes of RCC, renal medullary carcinoma and collecting duct carcinoma, appear to be derived from more distal elements of the nephron (Störkel et al, 1997; Zambrano et al, 1999; Abern et al, 2012).

Since the early 1990s the histologic classification of RCC has undergone several major revisions (see Table 57-7) (Zambrano et al, 1999; Zhou, 2009; Algaba et al, 2011). Traditionally, RCC was divided into four histologic subtypes: clear cell, granular cell, tubulopapillary, and sarcomatoid. On the basis of advances in the molecular genetics of RCC and a more discerning interpretation of histologic and ultrastructural features, a newer classification scheme was proposed by Kovacs (1993). This classification system was approved by an international consensus workshop of clinicians and researchers in the field (Weiss et al, 1995; Störkel et al, 1997; Zambrano et al, 1999). In this system, granular cell tumors were reclassified into other categories based on distinct histopathologic features, chromophobe RCC was recognized as a new RCC subtype, and sarcomatoid features were categorized as variants of other histologic subtypes rather than a distinct tumor type. Current practice is to identify the primary histologic subtype and comment on the presence and extent of sarcomatoid differentiation rather than to separate these tumors into a distinct category, although the prognostic implications have not changed (Cheville et al, 2004; Algaba et al, 2011). Depending on well-defined histologic and ultrastructural criteria, granular cell tumors were reclassified as papillary RCC or as eosinophilic variants of chromophobe RCC or combined with clear cell RCC. Another important development was the identification of renal medullary carcinoma that is common in young African-Americans with sickle cell trait (Davis et al, 1995; Abern et al, 2012). With additional advances in ancillary pathologic studies, including electron microscopy, immunohistochemistry, molecular genetics, and cytogenetics, several additional unique subtypes of RCC have been identified since implementation of the 1993 classification system. Based on these findings, an updated classification of malignant epithelial tumors of the kidney was

TABLE 57-6 Fuhrman’s Classification System for Nuclear Grade in Renal Cell Carcinoma

GRADE	NUCLEAR SIZE	NUCLEAR OUTLINE	NUCLEOLI
1	10 μm	Round, uniform	Absent or inconspicuous
2	15 μm	Irregular	Small (visible at 400× magnification)
3	20 μm	Irregular	Prominent
4	≥20 μm	Bizarre, often multilobed	Prominent, heavy chromatin clumps present

TABLE 57-7 Pathologic Subtypes of Renal Cell Carcinoma (RCC)

HISTOLOGY*	FAMILIAL FORM AND GENETIC FACTORS	GROSS CHARACTERISTICS	MICROSCOPIC PATHOLOGIC CHARACTERISTICS	OTHER CHARACTERISTICS
Clear cell RCC (70%-80%)	von Hippel-Lindau disease <i>VHL</i> gene (3p25-26) mutation or hypermethylation Chromosome 3p deletions Also, loss of chromosome 8p, 9p, 14q; gain of chromosome 5q	Well-circumscribed, lobulated, golden yellow tumor Necrosis and hemorrhage common Venous involvement also common Cystic degeneration	Hypervascular tumor Nests or sheets of clear cells with delicate vascular network IHC†: LMWCKs,‡ vimentin, EMA, CA-IX	Originates from proximal tubule Aggressive behavior more common Tumor shrinkage common with targeted molecular therapy May respond to immunotherapy
Multilocular cystic clear cell RCC (uncommon)	Identical to clear cell RCC	Well-circumscribed mass of small and large cysts	Cysts lined by single layer of grade 1 clear cells No expansive nodules of tumor cells	Almost uniformly benign clinical behavior
Papillary RCC (10%-15%)	Type 1: HPRCC syndrome Activation of <i>c-MET</i> oncogene (7q31-34) by mutation common in HPRCC but uncommon (~10%) in sporadic cases Trisomy of chromosome 7 and 17; loss of Y Type 2: HLRCC syndrome Fumarate hydratase gene (1q42-43) mutation in HLRCC	Fleshy tumor with fibrous pseudocapsule Necrosis and hemorrhage are common	Hypovascular tumor Papillary structures with single layer of cells around fibrovascular cores Type 1: basophilic cells with low-grade nuclei Type 2: eosinophilic cells with high-grade nuclei IHC: LMWCKs, CK7 (type 1 > type 2), AMACR	Originates from proximal tubule Commonly multicentric Common in ARCD Type 1: good prognosis Type 2: worse prognosis
Chromophobe RCC (3%-5%)	Birt-Hogg-Dubé syndrome Folliculin gene mutation (17p11) Loss of multiple chromosomes (1, 2, 6, 10, 13, 17, 21, Y)	Well-circumscribed, homogeneous Tan or light brown cut surface	“Plant cells” with pale cytoplasm, perinuclear clearing or “halo,” nuclear “raisins,” and prominent cell borders Positive Hale’s colloidal iron staining IHC: diffuse CK7	Originates from intercalated cells of collecting duct Generally good prognosis, although sarcomatoid variant associated with poor prognosis
Collecting duct carcinoma (<1%)	Unknown Multiple chromosomal losses	Firm, centrally located tumor with infiltrative borders Light gray to tan-white	Complex, highly infiltrative cords within inflamed (desmoplastic) stroma High-grade nuclei, mitoses	Originates from collecting duct Poor prognosis May respond to chemotherapy
Renal medullary carcinoma (rare)	Associated with sickle cell trait	Infiltrative, gray-white Extensive hemorrhage and necrosis	Poorly differentiated cells with lacelike appearance Inflammatory infiltrate	Originates from collecting duct Dismal prognosis
Unclassified RCC (1%-3%)	Unknown	Varied	Varied	Origin not defined Generally poor prognosis
RCC associated with Xp11.2 translocations/ <i>TFE3</i> gene fusions (rare)	Various mutations involving chromosome Xp11.2 resulting in <i>TFE3</i> gene fusion	Well-circumscribed, tan-yellow tumor	Variable; often clear cells with papillary architecture IHC: nuclear <i>TFE3</i>	Occurs in children and young adults; 40% of pediatric RCC t(X;17) presents with advanced stage and follows indolent course t(X;1) can recur with late lymph node metastases

presented by the World Health Organization in 2004 and remains current at this time (see Table 57-7) (Eble et al, 2004).

The World Health Organization classification reflects current understanding of RCC not as a single malignant neoplasm but rather as a group comprising several different tumor subtypes, each with a distinct genetic basis and unique clinical features. Important changes include the addition of several RCC subtypes with distinct pathologic and clinical features that were previously grouped within “conventional” or unclassified RCC. One example of this is RCC associated with Xp11.2 translocations/*TFE3* gene fusions, which has microscopic features of both clear cell and papillary RCC and occurs primarily in children and young adults (Argani et al, 2001; Camparo et al, 2008; Geller et al, 2008). Another is mucinous tubular and spindle cell carcinoma, which is indolent in almost all instances (Hes et al, 2002; Ferlicot et al, 2005; Fine et al, 2006). Sophisticated gene expression profiling and proteomic analyses support the individuality of each of these tumor subtypes and hold great promise for differentiating additional subtypes in the future (Yang et al, 2006; Jonasch et al, 2012). This is clearly a field in evolution, with changes stimulated by basic science advances and astute clinical observation.

Clear Cell Renal Cell Carcinoma

Clear cell RCC accounts for 70% to 80% of all RCCs, representing the garden variety of RCC formerly known as “conventional” RCC (Störkel et al, 1997; Deng and Melamed, 2012). These tumors are typically yellow when they are bivalved and are highly vascular, containing a network of delicate vascular sinusoids interspersed between sheets or acini of tumor cells (Fig. 57-8). On microscopic examination, clear cell RCC can include clear cell, granular cell, or mixed types. Clear cells are typically round or polygonal with abundant cytoplasm containing glycogen, cholesterol, cholesterol esters, and phospholipids, all of which are readily extracted by the solvents used in routine histologic preparations, contributing to the clear appearance of the tumor cells (Farrow, 1997). However, granular cells, which have eosinophilic cytoplasm and abundant mitochondria, can predominate. Three to five percent of clear cell RCCs demonstrate sarcomatoid features, and clear cell RCC is more likely to exhibit venous tumor extension than any other subtype of RCC (Rabbani et al, 2004). In general, patients with clear cell RCC have a worse prognosis compared with papillary or chromophobe RCC, even after stratification for stage and grade (Cheville

et al, 2003; Deng and Melamed, 2012). Chromosome 3 alterations occur in more than 90% of clear cell RCCs, leading to mutation or inactivation of the *VHL*, *PBRM1*, *SETD2*, or *BAP1* genes, which are all present on this portion of the genome (Cancer Genome Atlas Research Network, 2013; Linehan and Ricketts, 2013). The familial form of clear cell RCC, the von Hippel-Lindau syndrome, in which the *VHL* tumor suppressor gene is inactivated, has already been reviewed.

Papillary Renal Cell Carcinoma

Papillary RCC, which was also designated chromophilic RCC in previous classification schemes, is the second most common histologic subtype (Sukov et al, 2012). It represents 10% to 15% of all RCCs, with several features that distinguish it from clear cell RCC. On microscopic examination, most tumors in this category consist of basophilic or eosinophilic cells arranged in papillary or tubular configuration (Fig. 57-9). Gross features of papillary RCC include beige to white color, spherical boundary, and frequent hemorrhage, which may mimic cystic components radiologically. One unique feature of papillary RCC is its tendency toward multicentricity, which approaches 40% in many series and occurs more commonly in patients with end-stage renal failure and acquired renal cystic disease (Deng and Melamed, 2012).

Two distinct variants of papillary RCC have been described by characteristic cytogenetics, immunostaining profiles, and gene expression profiling (see Fig. 57-9B and C) (Störkel et al, 1997; Eble et al, 2004; Yang et al, 2005). Type 1 papillary RCC, the more common form, consists of basophilic cells with scant cytoplasm; type 2 papillary RCC includes potentially more aggressive variants with eosinophilic cells and abundant granular cytoplasm (Pignot et al, 2007). The two subtypes of papillary RCC

correspond with two familial RCC syndromes: HPRCC syndrome (type 1) and HLRCC syndrome (type 2). Although mounting molecular and genetic evidence indicate that these two subtypes appear to represent distinct entities, subclassification of papillary RCC into type 1 and type 2 is not routinely practiced within the community of genitourinary pathologists at present, and grade may be of greater prognostic significance (Yang et al, 2005; Klatte et al, 2010a, 2010b). The cytogenetic abnormalities associated with the more common type 1 papillary RCC are characteristic and include trisomy of chromosomes 7 and 17 and loss of the Y chromosome (Kovacs et al, 1989b). Other common findings include gain of chromosomes 12, 16, and 20 and loss of heterozygosity on chromosome 14 (Deng and Melamed, 2012). *VHL* mutations are rare in papillary RCC, confirming distinct genetic pathways to tumorigenesis (Kenck et al, 1996). Papillary RCC is more likely to be hypovascular, perhaps owing to the lack of *VHL* mutations that regulate VEGF, the primary proangiogenic molecule in RCC (Blath et al, 1976). As discussed earlier, activating mutations of the *c-MET* proto-oncogene located on chromosome 7 appears to be common and pathogenic in hereditary papillary RCC (Schmidt et al, 1997). Indeed, this genetic defect is now being targeted for novel treatment approaches with use of small molecule inhibitors (Jonasch et al, 2012; Harshman and Choueiri, 2013).

The prognosis associated with papillary RCC remains controversial. Five-year cancer-specific survival rates for patients with papillary RCC traditionally ranged from 86% to 92%, in part because papillary RCCs often presented with low stage and grade (Mancilla-Jimenez et al, 1976; Deng and Melamed, 2012). However, more recent studies that have utilized immunohistochemistry and cytogenetics to define papillary histology contain an increased proportion of high-grade and advanced tumors that, while still in the minority, can prove to be lethal. In part this is due to the

Figure 57-9. A, Papillary renal cell carcinoma (RCC) often presents with multiple small, mildly enhancing renal tumors as demonstrated on this computed tomography image. B, Microscopic appearance of type 1 papillary RCC demonstrating basophilic cells with scant cytoplasm and low-grade nuclei. C, In contrast, type 2 papillary RCC consists of eosinophilic cells with abundant granular cytoplasm and high-grade nuclei. (Courtesy Dr. Ming Zhou, Cleveland, OH.)

ineffectiveness of current systemic therapies against papillary RCC (Lager et al, 1995; Renshaw, 2002; Margulis et al, 2008; Amin and White, 2013). At present, most authors believe that papillary RCC, and type 1 papillary RCC in particular, carries a better prognosis than clear cell RCC when compared grade for grade and stage for stage (Deng and Melamed, 2012).

Papillary adenomas are small (≤ 5 -mm) tumors that resemble papillary RCC under the microscope, are often well encapsulated and low grade, and are commonly found at autopsy (Algaba et al, 2011). These lesions, which possess many of the same genetic alterations found in larger papillary RCCs, are benign neoplasms (see Chapter 56).

Chromophobe Renal Cell Carcinoma

Chromophobe RCC, first described by Thoenes and colleagues in 1985, is a distinctive histologic subtype of RCC that represents 5% of all RCCs and appears to be derived from the cortical portion of the collecting duct (Algaba et al, 2011). The tumor cells typically exhibit a relatively transparent cytoplasm with a fine reticular pattern that has been described as a “plant cell” appearance (Fig. 57-10). Most chromophobe RCCs are resistant to the pigment used during typical hematoxylin and eosin staining, but eosinophilic variants constitute about 30% of cases (Thoenes et al, 1988;

Nagashima, 2000). In either case, a perinuclear clearing or “halo” is typically found and electron microscopic findings consist of numerous 150- to 300-nm microvesicles, which are the single most distinctive and defining feature of chromophobe cell carcinoma. These microvesicles characteristically stain positive for Hale colloidal iron, indicating the presence of a mucopolysaccharide unique to chromophobe RCC (see Fig. 57-10). Immunohistochemistry typically reveals positive staining for pan-cytokeratin, epithelial membrane antigen, and parvalbumin and negative for vimentin and CD10 (Algaba et al, 2011). Genetic analysis typically reveals massive chromosomal losses, most frequently the whole chromosomes 1, 2, 6, 10, 13, 17, 21, and Y, and flow cytometric analysis has demonstrated hypodiploid DNA content in most cases (Bugert et al, 1997). Chromophobe RCC is commonly seen in the Birt-Hogg-Dubé syndrome, but most cases are sporadic (Linehan and Ricketts, 2013).

Most studies of the clinical behavior of chromophobe RCC suggest a better prognosis for localized chromophobe RCC than for clear cell RCC but a poor outcome in the subset of patients with sarcomatoid features or metastatic disease (Renshaw et al, 1996; Klatte et al, 2008). Most early reports suggested a tendency to remain localized despite growth to large size, as well as a predominance of low-grade disease (Thoenes et al, 1988). Subsequent reports have verified that chromophobe RCC generally presents at

Figure 57-10. A, Chromophobe renal cell carcinoma (RCC) typically appears as a well-circumscribed, homogeneous, tan tumor. B, Chromophobe RCC with admixture of classic (chromophobic) and eosinophilic cells. Characteristic features include distinct cytoplasmic borders, perinuclear “halos,” and nuclear “raisins.” The classic variant is notable for its “plant cell” appearance. C, Chromophobe RCC stains positive for Hale colloidal iron and demonstrates multiple microvesicles on analysis by electron microscopy. (Courtesy Dr. Ming Zhou, Cleveland, OH.)

an earlier stage, with more than 90% of patients remaining cancer free for 5 or more years after treatment (Klatte et al, 2008; Deng and Melamed, 2012). Limited data exist regarding treatment of metastatic chromophobe RCC, with most evidence suggesting limited activity of tyrosine kinase inhibitors and mTOR inhibitors in this population (Tannir et al, 2012; Kroeger et al, 2013). Clearly, further clinical evaluation will be required to identify the most effective therapeutic agents for patients with metastatic, non-clear cell RCC.

Collecting Duct Carcinoma

Carcinoma of the collecting ducts of Bellini is a relatively rare subtype of RCC, accounting for less than 1% of all RCCs (Algaba et al, 2011). Collecting duct carcinoma often presents earlier in life and with advanced stage (Tokuda et al, 2006; Karakiewicz et al, 2007c; Wright et al, 2009). Small collecting duct carcinomas can arise in a medullary pyramid, but most are large, infiltrative masses and extension into the cortex is common (Pickhardt et al, 2001; Deng and Melamed, 2012). On microscopic examination, these tumors consist of an admixture of dilated tubules and papillary structures typically lined by a single layer of cuboidal cells, often creating a cobblestone appearance. Deletions on chromosome 1q and monosomy of chromosomes 6, 8, 11, 18, 21, and Y have been reported, but the number of tumors analyzed thus far has been limited (Fuzesi et al, 1992; Steiner et al, 1996; Polascik et al, 2002). The characteristic immunophenotype of these tumors is coexpression of low- and high-molecular-weight cytokeratins and *Ulex europaeus* agglutinin-1 reactivity (Rumpelt et al, 1991). Positivity for E-cadherin and c-KIT help to distinguish this entity from aggressive papillary RCC, but this staining profile can also be present in urothelial carcinoma and differential diagnosis often requires careful examination of multiple sections (Kobayashi et al, 2008). Most reported cases of collecting duct carcinoma have been high grade, advanced stage, and unresponsive to conventional therapies (Tokuda et al, 2006; Karakiewicz et al, 2007c; Wright et al, 2009). Reflecting the fact that collecting duct carcinoma may share features in common with urothelial carcinoma, some patients with advanced collecting duct carcinoma have responded to cisplatin- or gemcitabine-based chemotherapy (Milowsky et al, 2002; Peyromaure et al, 2003; Oudard et al, 2007; Kobayashi et al, 2008; Dason et al, 2013). Other centers have used sunitinib and other VEGF inhibitors for this aggressive cancer with only marginal benefit (Ansari et al, 2009; Tannir et al, 2012).

Renal Medullary Carcinoma

Renal medullary carcinoma is a subtype of RCC that occurs almost exclusively in patients with the sickle cell trait. It is typically diagnosed in young African-Americans, often in the third decade of life, and many cases are both locally advanced and metastatic at the time of diagnosis (Davis et al, 1995; Swartz et al, 2002). Most patients do not respond to therapy and succumb to their disease in a few to several months. Mean survival in Davis and coworkers' series (1995), which consisted of 34 patients, was only 15 weeks. This tumor shares many histologic features with collecting duct carcinoma, and some consider it a subtype of collecting duct carcinoma or at least a closely related tumor (Swartz et al, 2002; Algaba et al, 2011). Renal medullary carcinoma is thought to arise from the calyceal epithelium near the renal papillae but is often highly infiltrative. The site of origin (renal papillae) and association with sickle cell trait suggest that a relatively hypoxic environment may contribute to tumorigenesis.

Sarcomatoid Differentiation

Sarcomatoid differentiation is found in 1% to 5% of RCCs, most commonly in association with clear cell RCC or chromophobe RCC, but variants of most other subtypes of RCC have been described (Ro et al, 1987; Shuch et al, 2012a). Most authors now believe that sarcomatoid lesions represent poorly differentiated regions of other histologic subtypes of RCC rather than independently derived tumors (DeLong et al, 1993; Eble et al, 2004). A thorough search for epithelial-derived malignant components is almost always fruitful; it is rare to find a truly pure sarcomatoid renal mass. For this reason, this entity is no longer recognized as a distinct histologic subtype of RCC (Eble et al, 2004). Sarcomatoid differentiation is characterized by spindle cell histology, positive staining for vimentin, infiltrative growth pattern, aggressive local and metastatic behavior, and poor prognosis (Fig. 57-11). Invasion of adjacent organs is common, and median survival has been less than 1 year in most series (Ro et al, 1987; Molina et al, 2011). Multimodal approaches should be considered if performance status allows, based on the extremely poor prognosis with surgery alone and selected reports demonstrating modest response rates in patients receiving IL-2-based immunotherapy, chemotherapy, or targeted molecular therapy after surgery (Shuch et al, 2012b).

Figure 57-11. A, Clear cell renal cell carcinoma (RCC) with sarcomatoid differentiation demonstrating extension into the perinephric fat. B, High-grade RCC with typical spindle cell appearance on the left indicating a component of sarcomatoid differentiation. (Courtesy Dr. Ming Zhou, Cleveland, OH.)

Unclassified Renal Cell Carcinoma

Unclassified RCC represents a small minority of cases (1% to 5%) of presumed RCC with features that remain indeterminate even after careful analysis (Crispen et al, 2010). Most are poorly differentiated and are associated with a highly aggressive biologic behavior and a particularly poor prognosis (Amin et al, 2002; Karakiewicz et al, 2007b). Included within this “catch-all” category are RCCs with extensive sarcomatoid differentiation and no discernible epithelial component. Advances in molecular diagnostics, such as gene expression profiling, may enable further classification of unusual tumors that previously would have fallen into this category and identify candidate pathways for targeted molecular therapeutics (Yang et al, 2006; Jonasch et al, 2012). Low-grade tumors such as hybrid oncocytic tumors, which are indeterminate between chromophobe RCC and oncocytoma, should not be placed into this category, which denotes poor prognosis.

Clinical Presentation

Because of the sequestered location of the kidney within the retroperitoneum, many renal masses remain asymptomatic and nonpalpable until they are locally advanced. With the more pervasive use of noninvasive imaging for the evaluation of a variety of nonspecific symptom complexes, more than 60% of RCCs are now detected incidentally (Silverman et al, 2008). Several studies have shown that such tumors are more likely to be confined to the kidney, and a positive impact on survival has been reported, although the contributions of lead and length time biases have not been defined (Tsui et al, 2000; Decastro and McKiernan, 2008; Kane et al, 2008).

Symptoms associated with RCC can be due to local tumor growth, hemorrhage, paraneoplastic syndromes, or metastatic disease (Box 57-4). Flank pain is usually due to hemorrhage and clot obstruction, although it can also occur with locally advanced or invasive disease. The classic triad of flank pain, gross hematuria, and palpable abdominal mass is now rarely found. This is fortunate because this constellation of findings almost always denotes advanced disease, and some refer to it as the “too late triad.” Before the advent of ultrasonography and CT, most patients with RCC presented with one or more of these signs or symptoms, and many were incurable. Other indicators of advanced disease include constitutional symptoms such as weight loss, fever, and night sweats, and physical examination findings such as palpable cervical lymphadenopathy, nonreducing varicocele, and bilateral lower extremity edema resulting from venous involvement. A minority of patients present with symptoms directly related to

metastatic disease, such as bone pain or persistent cough. A less common but important presentation of RCC is that of spontaneous perirenal hemorrhage, in which the underlying mass may be obscured. Zhang and colleagues (2002) have shown that more than 50% of patients with perirenal hematoma of unclear etiology have an occult renal tumor, most often AML or RCC. Repeat CT a few months later will often provide a definitive diagnosis.

Paraneoplastic syndromes are found in 10% to 20% of patients with RCC, and few tumors are associated with the diversity of such syndromes (Table 57-8). In fact, RCC was previously referred to as the internist’s tumor because of the predominance of systemic rather than local manifestations. Now, a more appropriate name would be the radiologist’s tumor, given the frequency of incidental detection (Parsons et al, 2001; Decastro and McKiernan, 2008). Nevertheless, it is still important to evaluate for paraneoplastic phenomena because they can be a source of major morbidity and can affect clinical decision making. Under normal circumstances, the kidney produces 1,25-dihydroxycholecalciferol, renin, erythropoietin, and various prostaglandins, all of which are tightly regulated to maintain homeostasis. RCC may produce these substances in pathologic amounts, and it may also elaborate a variety of other physiologically important factors, such as parathyroid hormone–like peptides, lupus-type anticoagulant, human chorionic gonadotropin, insulin, and various cytokines and inflammatory mediators. These substances are believed to be responsible for the development of constitutional symptoms such as weight loss, anemia, and paraneoplastic syndromes.

Hypercalcemia has been reported in up to 13% of patients with RCC and can be due to either paraneoplastic phenomena or osteolytic metastatic involvement of the bone (Klatte et al, 2007c; Schwarzbarg and Michaelson, 2009). The production of parathyroid hormone–like peptides is the most common paraneoplastic etiology, although tumor-derived 1,25-dihydroxycholecalciferol and prostaglandins may contribute in a minority of cases (Klatte et al, 2007c; Pepper et al, 2007). The expression of parathyroid hormone–like peptides is suppressed by the wild-type VHL protein, and these peptides may act as potent growth factors for RCC (Massfelder et al, 2004). The signs and symptoms of hypercalcemia are often nonspecific and include nausea, anorexia, fatigue, and decreased deep tendon reflexes. Medical management predominates and includes vigorous hydration followed by diuresis with furosemide and the selective use of bisphosphonates, corticosteroids, or calcitonin. Bisphosphonate therapy is now established as a standard of care for patients with hypercalcemia of malignancy, as long as renal function is adequate (Schwarzbarg and Michaelson, 2009). Zoledronic acid, 4 mg intravenously every 4 weeks, appears to be particularly effective in patients with RCC but must be withheld in the presence of renal insufficiency (Lipton et al, 2003; Schwarzbarg and Michaelson,

2009). Indomethacin has also proved useful in a minority of cases (Gold et al, 1996). More definitive management includes nephrectomy and occasional metastasectomy, depending on the clinical circumstances. Hypercalcemia related to extensive osteolytic metastases is much more difficult to palliate because it is not amenable to surgical approaches, but many such patients may respond to bisphosphonate therapy (Lipton et al, 2003; Young and Coleman, 2013). Some patients with hypercalcemia related to osteolytic metastases may also benefit from focused radiation therapy if limited sites of involvement can be identified.

Hypertension and polycythemia are other important paraneoplastic syndromes commonly found in patients with RCC (Moein and Dehghani, 2000). Hypertension associated with RCC can be secondary to increased production of renin directly by the tumor; compression or encasement of the renal artery or its branches, effectively leading to renal artery stenosis; or arteriovenous fistula within the tumor. Less common causes include polycythemia, hypercalcemia, ureteral obstruction, and increased intracranial pressure associated with cerebral metastases. Polycythemia associated with RCC can be due to increased production of erythropoietin, either directly by the tumor or by the adjacent parenchyma in response to hypoxia induced by tumor growth (Wiesener et al, 2007).

One of the more fascinating paraneoplastic syndromes associated with RCC is nonmetastatic hepatic dysfunction, or Stauffer syndrome, which has been reported in 3% to 20% of cases (Giannakos et al, 2005; Kranidiotis et al, 2009). Almost all patients with Stauffer syndrome have an elevated serum alkaline phosphatase level, 67% have elevated prothrombin time or hypoalbuminemia, and 20% to 30% have elevated serum bilirubin or transaminase levels. Other common findings include thrombocytopenia and neutropenia, and typical symptoms include fever and weight loss, which is not surprising given that many patients are found to harbor discrete regions of hepatic necrosis. Hepatic metastases must be excluded. Biopsy, when indicated, often demonstrates nonspecific hepatitis associated with a prominent lymphocytic infiltrate. Elevated serum levels of IL-6 have been found in patients with Stauffer syndrome, and it is believed that this and other cytokines may play a pathogenic role. Hepatic function normalizes after nephrectomy in 60% to 70% of cases. Persistence or recurrence of hepatic dysfunction is almost always indicative of the presence of viable tumor and thus represents a poor prognostic finding.

A variety of other less common but distinct paraneoplastic syndromes associated with RCC include Cushing syndrome, hyperglycemia, galactorrhea, neuromyopathy, clotting disorders, and cerebellar ataxia (Sufrin et al, 1989). In general, treatment of paraneoplastic syndromes associated with RCC has required surgical excision or systemic therapy and, except for hypercalcemia, medical therapies have not proved helpful.

Screening and Clinical Associations

A number of factors make screening for RCC appealing (Carrizosa and Godley, 2009). Most important, RCC remains primarily a surgical disease requiring early diagnosis to optimize the opportunity for cure. Unfortunately, our ability to salvage patients with advanced disease remains limited. Consistent with these observations, several studies have demonstrated an apparent advantage to early or incidental diagnosis of RCC (Lee et al, 2002; Leslie et al, 2003).

The primary factor that limits the widespread implementation of screening for RCC is the relatively low incidence of RCC in the general population (approximately 12 cases per 100,000 population per year) (Jemal et al, 2011). In this setting a screening test must be almost 100% specific to avoid an unacceptably high false-positive rate, which would lead to unnecessary, expensive, and potentially harmful diagnostic or therapeutic procedures. In addition, even if the test were 100% sensitive and specific, the yield from screening would be so low that it would not be considered cost effective (Cohn and Campbell, 2000; Carrizosa and Godley, 2009). Even when one considers populations with established risk factors

for RCC, such as male gender, increased age, and heavy tobacco use, generalized screening would be difficult to justify because the increase in relative risk associated with each of these factors is at best twofold to threefold (Cohn and Campbell, 2000; Carrizosa and Godley, 2009). Another confounding factor is the prevalence of clinically insignificant tumors such as renal adenomas, which are found at autopsy in 10% to 20% of individuals, and other benign or slow-growing tumors (Cohn and Campbell, 2000; Pantuck et al, 2000; Parsons et al, 2001). There is clearly a risk that such clinically insignificant lesions could be detected, leading to unnecessary evaluation and treatment (Pantuck et al, 2000; Parsons et al, 2001). All these factors recommend against generalized screening efforts for the detection of RCC.

Review of the literature describing the use of dipstick analysis for hematuria and ultrasonography or CT for screening for RCC supports these conclusions (Herts and Baker, 1995; Cohn and Campbell, 2000; Carrizosa and Godley, 2009). Urinalysis is simple and inexpensive, but the yield of RCC in several screening studies has been exceedingly low. In part, this may be because small RCCs are often not associated with hematuria (gross or microscopic) because this is a parenchymal rather than a urothelium-based malignant neoplasm. The incidence of RCC in ultrasound or CT screening studies has ranged from 23 to 300 per 100,000 population, much higher than expected. In addition, an increased proportion of organ-confined tumors has been found in screened populations compared with historical controls (Turney et al, 2006; Carrizosa and Godley, 2009). However, the incidence of RCC in these studies is still relatively low, and it is unlikely that such efforts would be considered cost effective. Overall, the yield of RCC in such studies is an order of magnitude lower than the yield from prostate-specific antigen–based screening for prostate cancer, and many of the same controversies about lead and length time biases that have plagued the debate about screening for prostate cancer also apply to RCC (Carter et al, 2013). Because of these considerations, it is difficult to justify generalized screening efforts for RCC given the currently available technology.

Several investigators are now reporting novel molecular assays to detect RCC-related biomarkers in the urine or serum that may substantially alter our perspective about screening for RCC. These assays can detect microsatellite alterations in the DNA, *VHL* gene mutations or hypermethylation, upregulation of angiogenic factors (including VEGF), or expression of RCC-specific proteins such as CA-IX and aquaporin-1 (Jonasch et al, 2012).

For now, however, the focus of screening for RCC must be on well-defined target populations, such as patients with end-stage renal disease and acquired renal cystic disease, tuberous sclerosis, and familial RCC (Box 57-5). Eighty percent of patients with end-stage renal disease eventually develop acquired renal cystic disease, and 1% to 2% of this subgroup develops RCC (Ishikawa et al, 2010). Overall, the relative risk of RCC in patients with end-stage renal disease has been estimated to be 5- to 20-fold higher than that in the general population (Farivar-Mohseni et al, 2006). Fifteen percent of patients with RCC in the setting of end-stage renal disease have metastases at the time of presentation, and many such patients die of malignant progression (Ishikawa et al, 2010; Hurst et al, 2011). Given these considerations, screening for RCC is recommended in this population, which is substantial, representing almost 300,000 patients in the United States alone. Concerns about screening this population include short life expectancy, increased incidence of adenomas (20% to 40% vs. 10% to 20% in the general population), complexity of imaging given the altered architecture associated with acquired renal cystic disease, and inevitable cost-related issues. A reasonable compromise for patients with end-stage renal disease is to target those without other major comorbidities, to delay screening until the third year on dialysis, and to take into account gender and type of renal replacement therapy, although data about the last factors are admittedly controversial (Carrizosa and Godley, 2009). Interestingly, renal transplant recipients remain at high risk for RCC in the native kidneys, with detection in between 1.4% and 2.3% of patients within 3 years of transplantation, leading to a recommendation for continued

BOX 57-5 Screening for Renal Cell Carcinoma: Target Populations**PATIENTS WITH END-STAGE RENAL DISEASE**

Screen only patients with long life expectancy and minimal major comorbidities

Periodic ultrasound examination or CT scan beginning during third year on dialysis

PATIENTS WITH KNOWN VON HIPPEL-LINDAU DISEASE

Obtain biannual abdominal CT or ultrasound study beginning at the age of 15 to 20 years

Periodic clinical and radiographic screening for nonrenal manifestations

RELATIVES OF PATIENTS WITH VON HIPPEL-LINDAU DISEASE

Obtain genetic analysis

If positive, follow screening recommendations for patients with known von Hippel-Lindau disease

If negative, less stringent follow-up is required

RELATIVES OF PATIENTS WITH OTHER FAMILIAL FORMS OF RENAL CELL CARCINOMA

Obtain periodic ultrasound or CT study and consider genetic analysis

PATIENTS WITH TUBEROUS SCLEROSIS

Periodic screening with ultrasound examination or CT scan

PATIENTS WITH AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Routine screening not justified

CT, computed tomography.

periodic radiologic screening even after transplantation (Ianhez et al, 2007; Hurst et al, 2010).

An increased incidence of RCC has also been debated in tuberous sclerosis, an autosomal dominant disorder in which patients can develop adenoma sebaceum (a distinctive skin lesion), epilepsy, mental retardation, and renal cysts and AMLs (Choyke et al, 2003; Lendvay and Marshall, 2003; Narayanan, 2003; Cohen and Zhou, 2005; Rakowski et al, 2006). Many cases of RCC in this syndrome have been characterized by early onset and multifocality, suggesting a genetic predisposition (Lendvay and Marshall, 2003). In addition, the Eker rat, which is mutant for the rodent homolog of the TSC2 gene responsible for the development of tuberous sclerosis in humans, develops RCC at high frequency, as do Tsc2-deficient knockout mice (McDorman and Wolf, 2002; Lendvay and Marshall, 2003). Such biologic and clinical observations argue in favor of an increased predisposition for RCC in this syndrome, which is consistent with most, although admittedly not all, relevant demographic data (Linehan and Ricketts, 2013). A reasonable conclusion is that periodic renal imaging should be pursued in patients with tuberous sclerosis; such a policy will also facilitate follow-up for the development and progression of AML.

Screening for RCC in autosomal dominant polycystic kidney disease (ADPKD) remains controversial. Imaging is extremely difficult in this population related to the altered intrarenal architecture, and several studies have found no significantly increased risk of RCC in ADPKD (Gregoire et al, 1987; Mosetti et al, 2003; Hajj et al, 2009; Jilg et al, 2013). The increased incidence of adenomas and other benign lesions in ADPKD also mitigates against a potential benefit of screening. Taken together, these

considerations suggest that routine screening for RCC in patients with ADPKD should not be pursued.

Special consideration should be given to von Hippel-Lindau disease in any discussion of the value of screening for RCC. This syndrome should be considered in any patient with early-onset or multifocal RCC or RCC in combination with any of the following: a history of visual or neurologic disorders; a family history of blindness, central nervous system tumors, or renal cancer; or coexistent pancreatic cysts, epididymal lesions, or inner ear tumors (Kim et al, 2010; Linehan and Ricketts, 2013). Patients suspected of having von Hippel-Lindau disease, or the appropriate relatives of those with documented disease, should strongly consider genetic evaluation. Patients with germline mutations of the VHL gene can be identified and offered clinical and radiographic screening that can identify the major manifestations of von Hippel-Lindau disease at a presymptomatic phase, allowing potential amelioration of the considerable morbidity associated with this syndrome (Linehan and Ricketts, 2013). Investigators at the National Institutes of Health have recommended that such patients be evaluated with (1) annual physical examination and ophthalmologic evaluation beginning in infancy; (2) estimation of urinary catecholamines at the age of 2 years and every 1 to 2 years thereafter; (3) MRI of the central nervous system biannually beginning at the age of 11 years; (4) ultrasound examination of the abdomen and pelvis annually beginning at the age of 11 years, followed by CT every 6 months if cysts or tumors develop; and (5) periodic auditory examinations (Linehan and Ricketts, 2013). Less intensive protocols have also been advocated, although all relevant organ systems should be addressed (Fraser et al, 2007). Individuals who are found to be wild type for both alleles of VHL also benefit because they can be spared much of the expense and anxiety associated with such intensive surveillance protocols.

Molecular screening is also available for patients suspected of having hereditary papillary RCC and other familial forms of RCC and should be discussed with appropriate family members (Linehan and Ricketts, 2013). Again, individuals at risk, as defined by the presence of mutations of the c-MET proto-oncogene or other relevant genetic alterations, and those with suggestive clinical or family histories should be evaluated with abdominal ultrasonography or CT at periodic intervals. Further testing may be indicated according to the syndrome involved.

Staging

Until the 1990s the most commonly used staging system for RCC was Robson's modification of the system of Flocks and Kadesky, and this schema is still embedded in the mindset of many older urologists (Fig. 57-12) (Robson, 1963; Robson et al, 1969). In retrospect, the limitations of this classification scheme are readily evident. The primary problem can be found in stage III, where tumors with lymphatic metastases, a very poor prognostic finding, were combined with those with venous involvement, many of which can be treated and potentially cured with an aggressive surgical approach (Gettman and Blute, 2002; Leibovich et al, 2003b; Nguyen and Campbell, 2006). Further imprecision resulted from the fact that the extent of venous involvement was not delineated in this system, and tumor size, an important prognostic parameter, was not incorporated. The tumor, node, and metastasis (TNM) system proposed by the Union International Contre le Cancer represents a major improvement because it defines the anatomic extent of disease more explicitly (Leung and Ghavamian, 2002; Nguyen and Campbell, 2006; Decastro and McKiernan, 2008).

In 2009 the American Joint Committee on Cancer proposed a revision of the TNM system that is now the recommended staging system for RCC (Table 57-9). The TNM classification for RCC has undergone several modifications in the past three decades in an effort to more accurately reflect tumor biology and prognosis. It is important to be cognizant of these changes when comparing studies from different eras (Nguyen and Campbell, 2006). In the 2002 version, stage T1 was subdivided to reflect data in the literature demonstrating excellent outcomes for patients with small

STAGING OF RENAL CELL CARCINOMA

Figure 57-12. Staging of renal cell carcinoma as proposed by Holland, in accordance with classification systems developed by Robson, Murphy, and Flocks and Kadesky. A, aorta; IVC, inferior vena cava. (From Holland JM. Cancer of the kidney: natural history and staging. Cancer 1973;32:1030. Copyright © 1973 American Cancer Society.)

(≤ 4 cm), unilateral, confined tumors managed by either partial or RN (Igarashi et al, 2001; Nguyen and Campbell, 2006). The most recent change for organ-confined tumors is a subdivision of T2 tumors (see Table 57-9), supported by a number of studies demonstrating prognostic relevance at the 10-cm breakpoint (Frank et al, 2005; Klatte et al, 2007b).

Other major revisions in 2009 included a reclassification of tumors with adrenal metastasis, venous thrombi, and lymphatic involvement, representing a substantial departure from previous staging paradigms for RCC. Contiguous extension of tumor into the ipsilateral adrenal gland is now classified as T4 and metastatic involvement of either adrenal as M1, reflecting likely patterns of dissemination. The poor prognosis of adrenal involvement from RCC is well documented and supported this important change (Thompson et al, 2005b; Nguyen and Campbell, 2006; Kirkali et al, 2007; von Knobloch et al, 2009). The favorable prognosis of isolated renal venous thrombi prompted a downgrading from stage T3b to stage T3a in the 2009 version (Moinzadeh and Libertino, 2004; Leibovich et al, 2005a; Shvarts et al, 2005a; Margulis et al, 2007b). Finally, lymphatic extension, which previously was subdivided based on the number of involved nodes, has now been compressed to simplify this aspect of the staging process, because prognostic relevance of the previous version was not observed (Edge et al, 2010). Recent studies suggesting independent prognostic power related to invasion of the sinus fat or collecting system remind us that continued re-evaluation and validation of the TNM

TABLE 57-9 International TNM Staging System for Renal Cell Carcinoma

T: PRIMARY TUMOR

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1a	Tumor ≤ 4.0 cm and confined to the kidney
T1b	Tumor > 4.0 cm and ≤ 7.0 cm and confined to the kidney
T2a	Tumor > 7.0 cm and ≤ 10.0 cm and confined to the kidney
T2b	Tumor > 10.0 cm and confined to the kidney
T3a	Tumor grossly extends into the renal vein or its segmental (muscle-containing) branches, or tumor invades perirenal and/or renal sinus fat but not beyond Gerota fascia
T3b	Tumor grossly extends into the vena cava below the diaphragm
T3c	Tumor grossly extends into the vena cava above the diaphragm or invades the wall of the vena cava
T4	Tumor invades beyond Gerota fascia (including contiguous extension into the ipsilateral adrenal gland)

N: REGIONAL LYMPH NODES

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph nodes metastasis
N1	Metastasis in regional lymph node(s)

M: DISTANT METASTASES

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present

STAGE GROUPING

Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T1 or T2	N1	M0
	T3	Any N	M0
Stage IV	T4	Any N	M0
	Any T	Any N	M1

system for RCC will be required to optimize its value moving into the future (Jeon et al, 2009; Verhoest et al, 2009; Anderson et al, 2011; Brookman-May et al, 2011). The T3 category in particular remains a matter of ongoing debate in the field (Bertini et al, 2009; Moch et al, 2009).

TNM staging classically is defined by the most advanced feature demonstrated by the tumor, yet important prognostic information can be lost in the process. Many renal tumors exhibit multiple adverse findings, such as high-level tumor thrombus along with ipsilateral adrenal involvement. Ideally all of the relevant anatomic staging information would be captured, at least parenthetically (e.g., "pT4 [ipsilateral adrenal involvement; also exhibiting IVC thrombus above the diaphragm]"). Future staging systems will need to capture all of this information, because a number of investigators have demonstrated a compromised prognosis for patients with multiple adverse factors (Leibovich et al, 2005a; Shvarts et al, 2005a; Terrone et al, 2006; Ficarra et al, 2007; Klatte et al, 2009a).

The clinical staging of renal malignant disease begins with a thorough history, physical examination, and judicious use of

laboratory tests (Nguyen and Campbell, 2006; Decastro and McKiernan, 2008). Systemic symptoms such as significant weight loss (>10% of body weight), cachexia, or poor performance status at presentation all suggest advanced disease, as do physical examination findings of a palpable mass or lymphadenopathy. A nonreducing varicocele and lower extremity edema suggest venous involvement. Significant anemia, hypercalcemia, abnormal liver function parameters or sedimentation rate, or elevated serum alkaline phosphatase or lactate dehydrogenase level all point to the probability of advanced disease (Nguyen and Campbell, 2006; Lane and Kattan, 2008).

The radiographic staging of RCC can be accomplished in most cases with a high-quality abdominal CT scan and a routine chest radiograph, with selective use of MRI and other studies as indicated (Choyke et al, 2001; Ng et al, 2008; Herts, 2009). MRI can be reserved primarily for patients with locally advanced malignant disease, equivocal venous involvement, or allergy to intravenous contrast material (Choyke et al, 2001; Zhang et al, 2007; Herts, 2009). CT findings suggestive of extension into the perinephric fat include perinephric stranding (Fig. 57-13), which is a nonspecific finding, or a distinct soft tissue density within the perinephric space, which is a more definitive but uncommon finding (Bechtold and Zagoria, 1997; Herts, 2009). Overall, the accuracy of CT or MRI for detection of involvement of the perinephric fat is low, reflecting the fact that extracapsular spread often occurs microscopically (Choyke et al, 2001; Kamel et al, 2004; Zhang et al, 2007). Ipsilateral adrenal involvement can be assessed with reasonable accuracy through a combination of preoperative CT and intraoperative inspection. Patients with an enlarged or indistinct adrenal gland on CT, extensive malignant replacement of the kidney, or a palpably abnormal adrenal gland are at risk for ipsilateral adrenal involvement and should be managed accordingly (Paul et al, 2001; Sawai et al, 2002; Zhang et al, 2007; Kobayashi et al, 2008; Ng et al, 2008; Lane et al, 2009c).

Enlarged hilar or retroperitoneal lymph nodes (2 cm or more in diameter) on CT almost always harbor malignant change, but this should be confirmed by surgical exploration or percutaneous biopsy if the patient is not a surgical candidate. Many smaller nodes prove to be inflammatory rather than neoplastic and should not preclude surgical therapy (Choyke et al, 2001; Israel and Bosniak, 2003; Ng et al, 2008; Herts, 2009). MRI can add specificity to the evaluation of retroperitoneal nodes by distinguishing vascular structures from lymphatic ones (Bassignani, 2006).

Figure 57-13. Computed tomography scan after administration of contrast agent shows right renal tumor with perinephric stranding suggesting invasion of the perinephric fat.

MRI is still the premier study for evaluation of invasion of tumor into adjacent structures and for surgical planning in these challenging cases (Pretorius et al, 2000; Choyke et al, 2001; Herts, 2009). Obliteration of the fat plane between the tumor and adjacent organs (e.g., the liver) on CT can be a misleading finding and should prompt further imaging with MRI. In reality, surgical exploration is often required to make an absolute differentiation.

The sensitivities of CT for detection of renal venous tumor thrombus and IVC involvement are 78% and 96%, respectively (Ng et al, 2008; Herts, 2009). CT findings suggestive of venous involvement include venous enlargement, abrupt change in the caliber of the vein, and filling defects. The diagnosis is strengthened by the demonstration of collateral vessels. Most false-negative findings occur in patients with right-sided tumors in whom the short length of the vein and the mass effect from the tumor combine to make detection of the tumor thrombus difficult (Herts, 2009). Fortunately, most such cases are readily identified and dealt with intraoperatively. MRI is well established as the premier study for the evaluation and staging of IVC tumor thrombus, although recent data suggest that multiplanar CT is likely equivalent (Pretorius et al, 2000; Aslam Sohaib et al, 2002; Zhang et al, 2007; Ng et al, 2008). Venacavography is now best reserved for patients with equivocal MRI or CT findings or for patients who cannot tolerate or have other contraindications to cross-sectional imaging. Transesophageal echocardiography also appears to be accurate for establishing the cephalad extent of the tumor thrombus, but it is invasive and provides no distinct advantages over MRI or CT in the preoperative setting (Glazer and Novick, 1997).

Metastatic evaluation in all cases should include a routine chest radiograph, systematic review of the abdominal and pelvic CT or MRI, and liver function tests (Griffin et al, 2007; Ng et al, 2008; Herts, 2009). Bone scintiscan can be reserved for patients with elevated serum alkaline phosphatase, bone pain, or poor performance status (Shvarts et al, 2004) and chest CT scan for patients with pulmonary symptoms or an abnormal chest radiograph (Choyke et al, 2001). Patients with locally advanced disease, enlarged retroperitoneal lymph nodes, or significant comorbid disease may mandate more thorough imaging to rule out metastatic disease and to aid in treatment planning (Choyke et al, 2001; Griffin et al, 2007). Positron emission tomography (PET) has also been investigated for patients with high risk of metastatic RCC, with most studies showing good specificity but suboptimal sensitivity. At present its best role is for patients with equivocal findings on conventional imaging. In this setting an abnormal PET scan may increase the concern about metastatic disease and could influence further evaluation and management (Griffin et al, 2007; Powles et al, 2007; Bouchelouche and Oehr, 2008). Biopsy of the primary tumor and/or potential metastatic sites is also selectively required as part of the staging process.

Prognosis

Important prognostic factors for cancer-specific survival in patients with nonmetastatic RCC include specific clinical signs or symptoms, tumor-related factors, and various laboratory findings (Box 57-6) (Lane and Kattan, 2008; Meskawi et al, 2012). Overall, tumor-related factors such as pathologic stage, tumor size, nuclear grade, and histologic subtype have the greatest utility on an independent basis. However, an integrative approach, combining a variety of factors that have proved to have independent value on multivariate analysis, appears to be most powerful (Meskawi et al, 2012). Patient-related factors such as age, CKD, and comorbidity have a significant impact on overall survival and should be a primary consideration during treatment planning for patients with localized RCC (Hollingsworth et al, 2006; Kutikov et al, 2010).

Clinical findings suggestive of a compromised prognosis in patients with presumed localized RCC include symptomatic presentation, weight loss of more than 10% of body weight, and poor performance status (Lane and Kattan, 2008). Anemia, thrombocytosis, hypercalcemia, albuminuria, and elevated serum alkaline

phosphatase, C-reactive protein, lactate dehydrogenase, or erythrocyte sedimentation rate, as well as other paraneoplastic signs or symptoms, have also correlated with poor outcomes for patients with RCC (Lane and Kattan, 2008; Magera et al, 2008b). Although abnormal values are more common in patients with advanced RCC,

some of these abnormalities, including hypercalcemia, anemia, and elevated erythrocyte sedimentation rate, were independent predictors of cancer-specific mortality in patients with localized clear cell RCC after accounting for other major prognostic factors (Magera et al, 2008b).

Pathologic stage has proved to be the single most important prognostic factor for RCC (Leibovich et al, 2005b; Lane and Kattan, 2008; Kanao et al, 2009). The RCC TNM staging system clearly distinguishes between patient groups with different predicted cancer-specific outcomes (Table 57-10), confirming that the extent of locoregional or systemic disease at diagnosis is the primary determinant of outcome for this disease (Lane and Kattan, 2008). Several studies demonstrate 5-year survival rates of 70% to 90% for organ-confined disease and document a 15% to 20% reduction in survival associated with invasion of the perinephric fat (Lane and Kattan, 2008). Renal sinus involvement is classified along with perinephric fat invasion as T3a, and several studies suggest that these patients may be at even higher risk for metastasis related to increased access to the venous system (Bonsib et al, 2000; Thompson et al, 2005a; Bertini et al, 2009; Jeon et al, 2009). Collecting system invasion has also been shown to confer poorer prognosis in otherwise organ-confined RCC (Uzzo et al, 2002; Klatte et al, 2007a; Verhoest et al, 2009; Anderson et al, 2011). Several reports have shown that most patients with direct or metastatic ipsilateral adrenal involvement, which is found in 1% to 2% of cases, eventually succumb to systemic disease progression, suggesting a hematogenous route of dissemination or a highly invasive phenotype (Sagalowsky et al, 1994; von Knobloch et al, 2009). The most recent staging system now reclassifies tumor as T4 if there is direct invasion of the adrenal gland or otherwise as M1, to reflect this poor prognosis (Thompson et al, 2005b; Edge et al, 2010).

Venous involvement was once thought to be a very poor prognostic finding for RCC, but several reports demonstrate that many patients with tumor thrombi can be salvaged with an aggressive surgical approach. These studies document 45% to 69% 5-year survival rates for patients with venous tumor thrombi as long as the tumor is otherwise confined to the kidney (Martinez-Salamanca et al, 2011). Patients with venous tumor thrombi and concomitant lymph node or systemic metastases have markedly decreased survival, and those with tumor extending into the perinephric fat have intermediate survival (Martinez-Salamanca et al, 2011). The most recent version of the TNM system advocates capturing all such adverse features during the staging process. Recent studies suggest that patients with microvascular invasion may have compromised outcomes compared to matched tumors

BOX 57-6 Prognostic Factors for Renal Cell Carcinoma

CLINICAL

Performance status
Systemic symptoms
Symptomatic vs. incidental presentation
Anemia
Hypercalcemia
Elevated lactate dehydrogenase
Elevated erythrocyte sedimentation rate

Data from Hafez et al, 1999; Leibovich et al, 2005a; Thompson et al, 2005a; Lane and Kattan, 2008; Campbell et al, 2009; Martinez-Salamanca et al, 2011; and Haddad and Rini, 2012.

without these features, indicating that even microscopic venous or lymphatic involvement may be a poor prognostic sign (Feifer et al, 2011; Kroeger et al, 2012).

The prognostic significance of the cephalad extent of tumor thrombus has been controversial, and it is difficult to compare various series because of selection biases and related covariables (Leibovich et al, 2005a; Wotkowicz et al, 2008). In several series the incidence of advanced locoregional or systemic disease increased with the cephalad extent of the tumor thrombus, accounting for the reduced survival associated with tumor thrombus extending into or above the level of the hepatic veins (Wotkowicz et al, 2008). However, other data suggest that the cephalad extent of tumor thrombus is not of prognostic significance as long as the tumor is otherwise confined (Libertino et al, 1987; Blute et al, 2007). Direct invasion of the wall of the vein appears to be a more important prognostic factor than level of tumor thrombus and is now classified as pT3c independent of the level of tumor thrombus (Hatcher et al, 1991; Zini et al, 2008).

The major drop in prognosis comes in patients whose tumor extends beyond the Gerota fascia to involve contiguous organs (stage T4) and in patients with lymph node or systemic metastases (Thompson et al, 2005b; Margulis et al, 2007a). Lymph node involvement has long been recognized as a dire prognostic sign because it is associated with 5- and 10-year survival rates of 5% to 30% and 0% to 5%, respectively (Phillips and Taneja, 2004; Crispen et al, 2011). Systemic metastases also portend a particularly poor prognosis for RCC, traditionally with 1-year survival of less than 50%, 5-year survival of 5% to 30%, and 10-year survival of 0% to 5%, although these numbers have improved modestly in the era of targeted treatments (Haddad and Rini, 2012). Patients presenting with synchronous metastases fare worse, with many patients dying of disease progression within 1 to 2 years (Leibovich et al, 2005a; Mekhail et al, 2005; Haddad and Rini, 2012; Heng et al, 2013). For patients with asynchronous metastases, the metastasis-free interval has proved to be a useful prognosticator because it reflects the tempo of disease progression (Maldazys and deKernion, 1986; Motzer et al, 2004; Mekhail et al, 2005). Other important prognostic factors for patients with systemic metastases include performance status, number and sites of metastases, anemia, hypercalcemia, elevated alkaline phosphatase or lactate dehydrogenase levels, thrombocytosis, and sarcomatoid histology (Lane and Kattan, 2008). The presence of bone, brain, and/or liver metastases and multiple metastatic sites have been associated with further compromise in prognosis (Mekhail et al, 2005; Escudier et al, 2007; McKay et al, 2014). These factors have been used to effectively categorize patients with metastatic RCC as low, intermediate, and poor risk, with corresponding differences in median survival (Motzer et al, 2004; Heng et al, 2013). These risk groups provide important information for determining the likelihood of benefit a patient may expect to receive after cytoreductive nephrectomy and/or resection of other metastatic disease.

Another significant prognostic factor for RCC is tumor size, which has proved to be an independent prognostic factor for both organ-confined and invasive RCC (Kattan et al, 2001; Kontak and Campbell, 2003; Lane and Kattan, 2008). To a large extent, this is due to a strong correlation between tumor size and pathologic tumor stage, but several studies have demonstrated that tumor size can function as an independent prognostic factor (Kattan et al, 2001; Sorbellini et al, 2005; Crispen et al, 2008a; Nguyen and Gill, 2009). Larger tumors are more likely to exhibit clear cell histology and high nuclear grade, and both of these factors correlate with a compromised prognosis (Frank et al, 2003; Lane et al, 2007a; Thompson et al, 2009). A review of 1771 patients with organ-confined RCC showed 10-year cancer-specific survival rates of 90% to 95%, 80% to 85%, and 75% for patients with pT1a, pT1b, and pT2 tumor, respectively (Patard et al, 2004a). Many other studies have also shown a particularly favorable prognosis for the unilateral pT1a tumors that are now being discovered with increased frequency. In series from the Cleveland Clinic and the Mayo Clinic, such tumors were associated with greater than 95% 5-year

cancer-specific survival rates, whether they were managed with nephron-sparing surgery or RN (Butler et al, 1995; Cheville et al, 2001; Lane et al, 2013b).

Other important prognostic factors for RCC include nuclear grade and histologic subtype. Several grading systems for RCC have been proposed on the basis of nuclear size and morphology and presence or absence of nucleoli. Unfortunately, interobserver variability is common in the assignment of nuclear grade; there is no ideal classification system that can overcome the subjectivity of this exercise. Nevertheless, almost all the proposed grading systems have provided prognostic information for RCC, and nuclear grade has proved in most cases to be an independent prognostic factor when subjected to multivariate analysis (Zisman et al, 2001; Lohse et al, 2002, 2005; True, 2002; Lang et al, 2005; Lane and Kattan, 2008; Ficarra et al, 2009).

Fuhrman's classification system has been the most generally adopted grading system for RCC. In the original report, the 5-year survival rates for grades 1 to 4 were 64%, 34%, 31%, and 10%, respectively, and nuclear grade proved to be the most significant prognostic factor for organ-confined tumors in this series (Fuhrman et al, 1982). Subsequent reports have demonstrated correlations between Fuhrman's nuclear grade and tumor stage, tumor size, venous tumor thrombi, and lymph node and systemic metastases (Ficarra et al, 2009). Although significant differences according to nuclear grade have been reported in series that have included patients with all types of RCC or clear cell RCC alone, the relevance of the Fuhrman classification system to evaluation of other subtypes of RCC is not entirely clear (see Pathology). Recent evidence suggests that Fuhrman grade has prognostic significance in papillary RCC, but that characteristics other than nuclear features may better predict the aggressiveness of chromophobe RCC and other oncocytic neoplasms (Klatte et al, 2010a; Finley et al, 2011; Delahunt et al, 2013; Meskawi et al, 2013).

Histologic subtype also carries prognostic significance, although, again, primarily at the ends of the spectrum. The presence of sarcomatoid differentiation or collecting duct, renal medullary, or unclassified histologic subtype denotes a poor prognosis (Zhou, 2009; Deng and Melamed, 2012). Several studies now suggest that clear cell RCC may have a worse prognosis on average compared with papillary or chromophobe RCC, although there are clearly poorly differentiated tumors in each of these subcategories that can be lethal (Teloken et al, 2009; Leibovich et al, 2010; Deng and Melamed, 2012). Finally, several subtypes of RCC are predictably indolent, including multiloculated cystic clear cell RCC and mucinous tubular and spindle cell carcinoma.

A variety of molecular factors have correlated with outcomes for RCC in observational studies and will likely prove to be useful in the future (Jonasch et al, 2012; Keefe et al, 2013). This includes hypoxia-inducible factors, genes controlling cellular oxygen sensing, maintenance of chromatin states, costimulatory molecules, cell cycle regulators, and adhesion molecules in addition to many others (Box 57-7) (Jonasch et al, 2012). Aggressive cancers demonstrate downregulation of genes involved in the TCA cycle and upregulation of the pentose phosphate pathway (Cancer Genome Atlas Research Network, 2013). In general, clinical validation has not yet been achieved with any of these factors and they remain primarily investigational.

Several investigators have now developed tools that integrate clinical risk factors with pathologic factors, and this has greatly improved our predictive capacity for patients with RCC. Incorporation of the strongest predictors into a nomogram is one way to provide an individual assessment of risk that clinicians can use during patient counseling (see Table 57-11 for a comprehensive list of published integrated staging systems). Kattan and colleagues (2001) developed the first of these for RCC, and several nomograms have been introduced subsequent to this. One such nomogram incorporating stage, size, grade, and symptoms at presentation has been validated using multi-institutional data sets and outperforms several of the other existing prognostic tools for localized RCC (Fig. 57-14) (Karakiewicz et al, 2007a).

BOX 57-7 Molecular Prognostic Factors for Renal Cell Carcinoma (RCC)

Dozens of genes that may have prognostic or therapeutic significance for patients with RCC have been identified using high-throughput technologies (Takahashi et al, 2006; Zhao et al, 2006; Brannon et al, 2010; Keefe et al, 2013). Gene expression profiling (cDNA microarrays) can quantify the levels of thousands of individual messenger RNA transcripts within an individual tumor sample. Alterations in gene expression can then be correlated with the amount and location of specific gene products (proteins) using immunohistochemical staining of cancer specimens (Kim et al, 2004a; Parker et al, 2009). Construction of tissue microarrays can facilitate the screening of hundreds of tumors, but interpretation of results can be challenging due to tumor heterogeneity and the selection of only a small amount of tissue for analysis. Furthermore, when evaluating the potential value of a new marker, it is important to consider its contribution after accounting for other known prognostic factors (George and Bukowski, 2007; Tunuguntia and Jorda, 2008).

Several molecular markers appear to serve as independent prognostic factors for RCC and have provided important insights into tumor biology (see *Tumor Biology and Clinical Implications*) (Bui et al, 2001; Han et al, 2003; Crispen et al, 2008a; Nogueira and Kim, 2008; Parker et al, 2009). One such factor is CA-IX, which is regulated by the *VHL* gene and overexpressed in most clear cell RCCs (Bui et al, 2003, 2004; Leibovich et al, 2007). Although initial studies indicated that decreased expression of CA-IX is independently associated with poor survival in patients with metastatic RCC (Bui et al, 2003; Kim et al, 2005), this association does not appear to apply for patients with localized disease (Kim et al, 2005; Leibovich et al, 2007). CA-IX also may serve as a marker for response to systemic therapy, making CA-IX immunostaining of particular value for patients with advanced disease (Bui et al, 2004; Atkins et al, 2005; Cho et al, 2007). B7-H1 is a T-cell coregulatory molecule that is a strong independent predictor of disease progression for RCC (Thompson et al, 2006; Parker et al, 2009). This association holds even after accounting for other molecular factors and established clinical and pathologic predictors (Krambeck et al, 2007; Parker et al, 2009). Increased proliferative index as assessed by Ki-67 has also been correlated with reduced survival in clear cell RCC (Bui et al, 2004; Klatte et al, 2009b; Parker et al, 2009). Although initial data indicated that Ki-67 expression was a surrogate for histologic necrosis, more recent studies have found Ki-67 to be an independent predictor and have incorporated it into predictive algorithms (Tollefson et al, 2007; Klatte et al, 2009b; Parker et al, 2009). Other factors that appear to be useful include cell cycle regulators, such as the tumor suppressor gene *TP53* (Kim et al, 2004a; Shvarts et al, 2005b; Klatte et al, 2009b); various growth factors and their receptors, including members of the VEGF family (Jacobsen et al, 2000; Phyoc et al, 2008; Rivet et al, 2008; Klatte et al, 2009b); adhesion molecules; and other factors, such as survivin (Parker et al, 2006, 2009; Byun et al, 2007; Krambeck et al, 2007).

Two other integrated staging systems that have been used to risk stratify patients for clinical trials are the UCLA Integrated Staging System (UISS) and the Mayo Clinic Stage, Size, Grade and Necrosis (SSIGN) score. The UISS was developed based on multivariate analysis revealing three independent prognostic factors for RCC, namely TNM stage, performance status, and tumor grade (Zisman et al, 2001). The UISS was subsequently

modified to identify patients with localized or metastatic disease at low, intermediate, and high risk of disease progression and has been validated internally and externally (Zisman et al, 2002; Patard et al, 2004b; Cindolo et al, 2005, 2008; Parker et al, 2009). Molecular factors such as *TP53*, Ki-67, VEGF family members, and CA-IX have also been incorporated into UISS-based algorithms to predict outcomes for patients with localized or metastatic RCC (Kim et al, 2005; Klatte et al, 2009a).

The SSIGN score can be used to estimate cancer-specific survival based on TNM stage, tumor size, nuclear grade, and presence of tumor necrosis (Frank et al, 2002). The SSIGN score has been validated in multiple data sets, but the inclusion of histologic necrosis as a predictor limits its clinical usefulness (Ficarra et al, 2006, 2009; Fujii et al, 2008; Zigeuner et al, 2010). The group at the Mayo Clinic has also developed a dynamic outcome prediction model that provides patients with cancer-specific survival rates that improve as the disease-free interval following surgery increases and a model in which molecular data are incorporated with the SSIGN components into a BioScore (Thompson et al, 2007c; Parker et al, 2009).

TNM staging systems and prognostic algorithms have different purposes. The TNM staging system is used to provide a universal language for communication between clinicians and patients and is based solely on the anatomic extent of cancer dissemination. A wealth of literature now supports the notion that algorithms that incorporate multiple predictive elements, such as nomograms and artificial neural networks, outperform risk assessment based on expert opinion or simpler models, such as classic staging systems (Ross et al, 2002; Isbarn and Karakiewicz, 2009; Shariat et al, 2009). The development and use of these integrated staging systems can help guide counseling and follow-up of patients with RCC and identify patients more likely to benefit from specific interventions.

TREATMENT OF LOCALIZED RENAL CELL CARCINOMA

Localized renal masses have increased in incidence related to more widespread use of cross-sectional imaging and now represent a relatively common clinical scenario (Lipworth et al, 2006; Jemal et al, 2009; Miller et al, 2010a). Our perspectives about clinical T1 renal masses have changed substantially in the past two decades. Previously, all were presumed to be malignant and managed aggressively, most often with RN. We now recognize great heterogeneity in the tumor biology of these lesions, and multiple management strategies are now available, including RN, partial nephrectomy (PN), thermal ablation (TA), and active surveillance (AS) (Kunkle et al, 2008; Campbell et al, 2009; Aron et al, 2010; Van Poppel et al, 2011a; Volpe et al, 2011; Kim and Thompson, 2012) (Fig. 57-15). Concepts that were once controversial, such as elective PN, are now accepted as standards of care (Kunkle et al, 2008; Campbell et al, 2009). A greater understanding of the tumor biology and appreciation of the deleterious functional consequences of RN has stimulated a reassessment of this field (Russo and Huang, 2008; Campbell et al, 2009). Ongoing debates about the relative merits of PN and RN and other management strategies have spawned a vibrant literature over the past few years.

Overall, about 20% of solid, enhancing, clinical T1 renal masses are benign, most often oncocytomas or atypical AMLs, although the incidence of benign pathology can vary greatly in different subpopulations (Frank et al, 2003; Russo and Huang, 2008; Campbell et al, 2009; Gill et al, 2010a). Young to middle-age women, in particular, are more likely to have benign pathology, as high as 40% in some series (Eggerer et al, 2004). One potential explanation is that some benign renal masses, such as cystic nephroma and atypical AML, may be influenced by the hormonal milieu and are thus more common in women. In contrast, the proportion of benign tumors appears to increase gradually in males as they age (Lane et al, 2007a). An even more important determinant of benign pathology is tumor size, with multiple studies confirming this (Campbell et al, 2009). Frank and colleagues

TABLE 57-11 Integrated Predictive Tools for Renal Cell Carcinoma (RCC)

STUDY	SETTING, SUBTYPE	PATIENTS, SOURCE	PROGNOSTIC INDICATORS	OUTCOME OF INTEREST	ACCURACY (%), FORMAT
PREOPERATIVE					
Lane et al (2007a)	Localized renal tumors amenable to PN	862; Single institution	Tumor size, symptoms, gender, age, smoking	Histology	56%-64% (internal) Nomogram

CA-IX, carbonic anhydrase-IX; CRP, C-reactive protein; PN, partial nephrectomy; RENAL, Radius, Endophytic vs. exophytic, Nearness to collecting system, Anterior/posterior, and Location relative to polar lines; SSIGN, Mayo Clinic Stage, Size, Grade and Necrosis Score; TNM, tumor, node, metastasis; UISS, UCLA Integrated Staging System; VEGF, vascular endothelial growth factor; VEGFR, VEGF receptor.

Modified from Meskawi M, Sun M, Trinh QD, et al. A review of integrated staging systems for renal cell carcinoma. Eur Urol 2012;62:303-14.

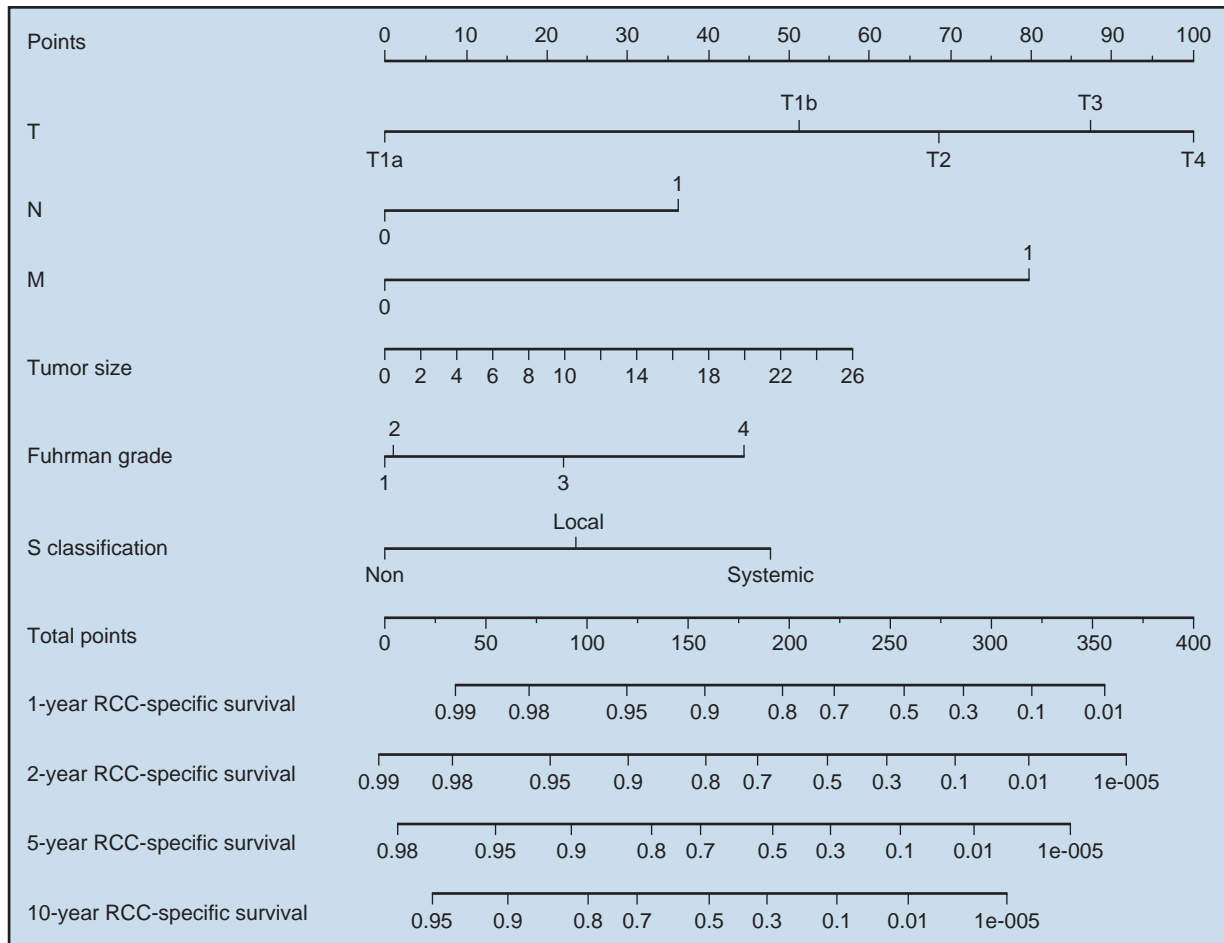

Figure 57-14. Postoperative nomogram predicting renal cell carcinoma (RCC)-specific survival at 1, 2, 5, and 10 years after nephrectomy. To use, locate the tumor stage on the T axis. Draw a line upward to the Points axis to determine how many points toward survival the patient receives for this parameter. Repeat this process for the other axes—N, M, Tumor size, Fuhrman grade, and S classification (nonsymptomatic, local symptoms, systemic symptoms)—each time drawing straight upward to the Points axis. Sum the points achieved for each predictor and locate the sum on the Total points axis. Draw a straight line down to find the probability that the patient will remain free of death from RCC for 1, 2, 5, or 10 years, assuming the patient does not die of another cause first. (From Karakiewicz PI, Briganti A, Chun FK, et al. Multi-institutional validation of a new renal cancer-specific survival nomogram. *J Clin Oncol* 2007;25:1316–22.)

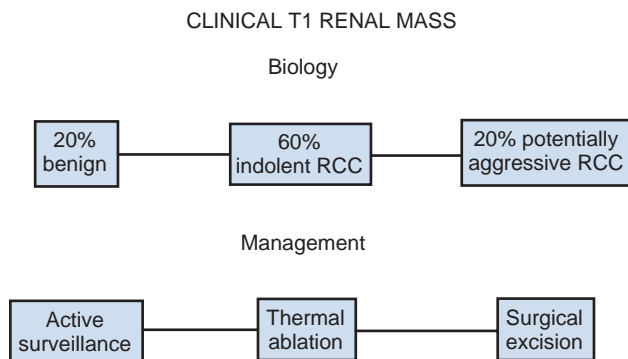

Figure 57-15. Clinical T1 renal masses are heterogeneous, with 20% benign and only about 20% exhibiting potentially aggressive features. Management options have expanded greatly, ranging from radical nephrectomy, the previous standard, to active surveillance. RCC, renal cell carcinoma.

(2003) have demonstrated a direct relationship between tumor size and the incidence of malignancy. In their series, 30% of tumors less than 2 cm were benign, compared with 21% of tumors between 2 and 4 cm. In contrast, only 9.5% of clinical T1b tumors were benign. Tumor size has also correlated with biologic aggressiveness for clinical T1 renal masses, as reflected by high tumor grade, locally invasive phenotype, or adverse histologic subtype. In the study by Frank and colleagues (2003), such adverse findings were uncommon in tumors less than 4 cm diameter. In this subset only 1.7% demonstrated invasion of the perinephric fat, 0.7% had venous involvement, 0.6% had lymph node involvement, and only 15% were high grade. Such features were more commonly observed in clinical T1b tumors in this and other series. Other studies suggest a cut point at 3 cm, with tumors larger than this much more likely to exhibit potentially aggressive histopathologic features (Remzi et al, 2006; Pahernik et al, 2007). Surveillance studies confirm a slow growth rate and low risk of metastasis for many small renal tumors (Bosniak et al, 1995; Kunkle et al, 2007, 2008; Abouassaly et al, 2008; Crispen et al, 2009).

Other clinical factors such as patient age and sex, symptomatic presentation, and smoking history have also been studied, although none of these factors can provide substantial predictive value with respect to tumor aggressiveness (Lane et al, 2007a). Current algorithms incorporating clinical and radiographic factors to predict tumor aggressiveness are very limited in their accuracy, with concordance indices less than 0.60, not much better than a coin flip (Lane et al, 2007a; Kutikov et al, 2011). Conventional renal mass biopsy can substantially improve on this, having demonstrated reasonable accuracy for assessment of tumor histology, and should be considered in patients who are candidates for a wide range of management strategies (Lane et al, 2008; Schmidbauer et al, 2008; Leveridge et al, 2011; Samplaski et al, 2011; Volpe et al, 2012). Some centers are now routinely performing renal mass biopsy in the evaluation of localized renal masses, and are reporting encouraging results regarding potential clinical utility (Halverson et al, 2013). However, younger, healthy patients who are unwilling to accept the uncertainty associated with renal mass biopsy and older, frail patients who will be managed conservatively independent of biopsy results should still be managed without a biopsy. An alternative to renal mass biopsy has recently been reported, namely PET scanning coupled with administration of radioactively labeled anti-CA-IX monoclonal antibody. Specificity for clear cell RCC and type 2 papillary RCC has been demonstrated, potentially allowing for noninvasive risk stratification for patients with localized renal masses (Divgi et al, 2013).

Renal Function after Surgery for Localized Renal Cell Carcinoma

Notwithstanding advances in our understanding of the genetics and biology of RCC, surgery remains the mainstay for curative treatment of this disease. The objective of surgical therapy is to excise all tumor with an adequate surgical margin. Simple nephrectomy was practiced for many decades but was supplanted by RN when Robson and colleagues (1969) established this procedure as the gold standard curative operation for localized RCC. RN is still a preferred option for many patients with localized RCC, such as those with very large tumors (most clinical T2 tumors) or the relatively limited subgroup of patients with clinical T1 tumors that are not amenable to nephron-sparing approaches (Nguyen et al, 2008a). RN has more recently fallen out of favor for small renal tumors because of concerns about CKD, and should only be performed when necessary in this population (Nakada, 2005; Nguyen et al, 2008a; Russo and Huang, 2008; Campbell et al, 2009).

The main concern with RN is that it predisposes to CKD, which is potentially associated with morbid cardiovascular events and increased mortality rates. Several studies have shown an increased risk of CKD on longitudinal follow-up after RN, including a landmark study from the Memorial Sloan Kettering Cancer Center that looked at 662 patients with a small solitary tumor, a normal opposite kidney, and a "normal" serum creatinine level—essentially patients who would be considered for elective PN (Huang et al, 2006; Russo and Huang, 2008). The first major finding was that 26% of this patient population had preexisting grade 3 CKD (estimated glomerular filtration rate [eGFR] <60 mL/min/1.73 m²), demonstrating that this patient population is substantially different than the kidney transplant donor population that is often considered analogous. In reality, the donor population is not comparable because it is carefully screened to exclude CKD and related comorbidities. The second major finding was that the incidence of grade 3 CKD was much more common after RN than PN: 65% versus 20%, respectively ($P < .001$). More severe CKD (eGFR <45 mL/min/1.73 m²) was also much more common after RN than PN: 36% versus 5%, respectively ($P < .001$).

Several studies illustrate the potential negative implications of CKD, including a population-based study that followed more than a million subjects for 2.8 years and reported increased rates

of cardiovascular events and death as the degree of CKD worsened even after controlling for hypertension, diabetes, and other potential confounding factors (Go et al, 2004). The relative risks of cardiovascular events were 1.4, 2.0, 2.8, and 3.4 for eGFR of 45 to 60, 30 to 45, 15 to 30, and less than 15 mL/min/1.73 m², respectively. Relative death rates were 1.2, 1.8, 3.2, and 5.9 for these same subgroups, respectively. These data highlight the potential need to optimize renal function and underscore nephron sparing as an important principle in the management of clinical T1 renal masses, particularly small renal masses (Miller et al, 2008; Russo and Huang, 2008; Thompson et al, 2008; Campbell et al, 2009; Huang et al, 2009; Lane et al, 2009b).

Multiple retrospective series in the past 5 years have compared PN versus RN for the management of clinical T1 renal masses, almost uniformly concluding in favor of PN (Kim et al, 2012b; MacLennan et al, 2012). A recent meta-analysis of this literature looked at over 30 such studies and revealed the following statistically significant results in favor of PN: (1) a 61% risk reduction for the development of severe CKD, (2) a 19% risk reduction in overall mortality, and (3) a 29% risk reduction in cancer-specific mortality. The retrospective nature of these studies naturally raises concern about selection bias, and the third result listed above substantiates this concern. Clearly, PN is not a stronger oncologic intervention than RN, and the only reasonable way to explain an advantage for PN with respect to cancer-specific outcomes is selection bias. One cannot help but wonder whether selection bias may also be contributing to the overall survival advantage for PN (Campbell et al, 2013; Shuch et al, 2013a).

A prospective trial of RN versus PN was reported in 2011 that has stimulated great controversy. This trial, EORTC 30904, randomized over 500 patients with small (<5.0-cm) unifocal tumors and a normal contralateral kidney to RN versus elective PN, and showed an advantage for RN in terms of lower perioperative morbidity, while PN provided better renal functional outcomes (Van Poppel et al, 2011b). Oncologic events were uncommon, as expected for small renal masses, and similar in both groups. Based on prevailing paradigms, we would have expected better overall survival in the PN group, primarily driven by reduced cardiovascular morbidity. However, 10-year overall survival was in reality better for RN than PN (81% vs. 76%, respectively, $P < .05$), and cardiovascular deaths were less common in the RN group. This trial has some flaws and most thought leaders in the field, including the authors, do not choose to interpret it literally. However, EORTC 30904 has stimulated further research by suggesting that the functional advantage of PN in the setting of a normal contralateral kidney may not be as beneficial as previously believed.

Further studies have suggested that there may be a difference between CKD resulting from medical causes (CKD-M) and that resulting from surgery (CKD-S). Patients with CKD caused by hypertension or diabetes will continue to suffer from these comorbidities, and will likely experience progressive decline in renal function, eventually affecting survival. The medical literature confirms this, as outlined above (Go et al, 2004). However, patients with CKD primarily resulting from surgical removal of nephrons typically do not need further surgery, and might stabilize (Campbell et al, 2013). This hypothesis was recently tested in a series of over 4000 patients with localized RCC managed with PN or RN, including 1182 with CKD prior to management (CKD-M) and 927 who developed CKD only after surgery (CKD-S) (Lane et al, 2013a). The mean annual decline of renal function was 4.7% in patients with CKD-M compared to only 0.7% for the CKD-S group. In addition, the survival of patients with CKD-S was very similar to the group of patients with no CKD, and substantially better than patients with CKD-M. Further research will be required, but such studies suggest that the impact of CKD resulting from surgery may not be as great as previously thought, at least in the setting of a normal contralateral kidney.

The recent controversies discussed above have created some confusion for those at the periphery of this field, but certain fundamental principles can be supported, as illustrated in the Key Points box.

KEY POINTS: PARTIAL VERSUS RADICAL NEPHRECTOMY

- PN is preferred for small renal masses (T1a, <4.0 cm) whenever feasible, because RN represents gross overtreatment for most such lesions, which tend to have limited biologic potential.
- PN is also strongly preferred whenever preservation of renal function is potentially important, such as patients with pre-existing CKD, those with an abnormal contralateral kidney, or those with multifocal or familial RCC.
- Larger renal tumors (clinical stages T1b and T2) have increased oncologic potential and have often already replaced a substantial portion of the parenchyma, leaving less to be saved by PN. In the setting of a normal contralateral kidney, the relative merits of PN versus RN can be debated in this population.
- Well-designed randomized, prospective trials will be required to provide higher quality data and to allow for more rational management of patients with localized renal tumors.

Radical Nephrectomy

The prototypical concept of RN encompasses the basic principles of early ligation of the renal artery and vein, removal of the kidney with primary dissection external to the Gerota fascia, excision of the ipsilateral adrenal gland, and performance of an extended lymphadenectomy from the crus of the diaphragm to the aortic bifurcation (O'Malley et al, 2009b). Controversy has arisen regarding the need for many of these practices on a routine basis (Lam et al, 2004). Performance of a perifascial nephrectomy is of undoubted importance during RN for preventing postoperative local tumor recurrence because approximately 25% of clinical T1b/T2 RCCs manifest perinephric fat involvement (Lam et al, 2007; Thompson et al, 2007a). Preliminary renal arterial ligation remains an accepted practice; however, in large tumors with abundant collateral vascular supply, it is not always possible to achieve complete preliminary control of the arterial circulation (O'Malley et al, 2009b). It has been well demonstrated that removal of the ipsilateral adrenal gland is not routinely necessary in the absence of radiographic adrenal enlargement unless the malignant lesion extensively involves the kidney and/or is locally advanced (Lane et al, 2009c; Bratslavsky and Linehan, 2011; Weight et al, 2011). Location of the tumor in the upper portion of the kidney immediately adjacent to the adrenal gland is another relative indication for adrenalectomy (Siemer et al, 2004; Lane et al, 2009c).

The need for an extensive lymphadenectomy in all patients undergoing RN also remains controversial, and a randomized study of lymphadenectomy versus controls at the time of renal surgery failed to show a distinct advantage (Phillips and Taneja, 2004; Patard et al, 2005; Leibovich and Blute, 2008; Blom et al, 2009). There are several factors that mitigate against a benefit of routine lymphadenectomy (Leibovich and Blute, 2008; O'Malley et al, 2009b). RCC metastasizes through the bloodstream independent of the lymphatic system in many patients, and the lymphatic drainage of the kidney is highly variable. Even an extensive retroperitoneal dissection may not remove all possible sites of metastasis. Many believe that only a relatively small percentage of patients (<2% to 3%) are likely to benefit from routine lymphadenectomy, namely, the subset of patients with micrometastatic disease (Giuliani et al, 1990; Leibovich and Blute, 2008; O'Malley et al, 2009b). In all likelihood, the involved lymph nodes in many of these patients would be removed by conventional RN, which incorporates the renal hilar and immediately adjacent paracaval or para-aortic lymph nodes. At present, the need for routine performance of an extended lymphadenectomy in all cases of RN is not well defined and most urologists perform this selectively based on age, comorbidities, and tumor characteristics (see *Treatment of*

Locally Advanced Renal Cell Carcinoma) (Blute et al, 2004a; Daneshmand et al, 2005; Leibovich and Blute, 2008; Crispen et al, 2011).

Open surgical techniques for RN are described in detail in Chapter 60. The surgical approach for RN is determined by the size and location of the tumor as well as by the body habitus of the patient (Diblasio et al, 2006). The operation is usually performed through a transperitoneal incision to allow abdominal exploration for metastatic disease and early access to the renal vessels. The authors prefer an extended subcostal incision for most patients undergoing open RN, although a midline incision is a reasonable alternative, and the thoracoabdominal approach can be useful for very large and potentially invasive tumors involving the upper portion of the kidney. An extraperitoneal flank incision may be appropriate in elderly patients or patients of poor surgical risk, but exposure can be limiting, particularly for large tumors or those with contentious hilar anatomy (Diblasio et al, 2006; Russo, 2006). In reality, most of these patients are now managed with a laparoscopic approach in this era.

Laparoscopic RN is now established as a less morbid alternative to open surgery in the management of low- to moderate-volume (10 to 12 cm or smaller), localized RCCs with no local invasion, limited or no venous involvement, and manageable lymphadenopathy. Current minimally invasive techniques allow replication of the important tenets of RN, and oncologic and other outcome data reflect this at several centers (Wille et al, 2004; Permpongkosol et al, 2005; Berger et al, 2009a). A variety of approaches, including transperitoneal, retroperitoneal, and hand-assisted laparoscopic RN, have been popularized and are described elsewhere in this text (see Chapter 61) (Nadler et al, 2006; Chung et al, 2007; Kawauchi et al, 2007; Miyake et al, 2007). The current data suggest that elderly and morbidly obese patients, those with a history of previous abdominal surgery, and those with large tumor size may also be considered for minimally invasive renal surgery, although selection of patients must be judicious and surgical expertise and experience should also be taken into account (Viterbo et al, 2005; Feder et al, 2008; Gabr et al, 2008; Tan et al, 2011). One concern is that laparoscopic RN has become particularly appealing to patients and physicians alike, and this has likely been a major driver in the overutilization of RN for small renal masses over the past several years (Fig. 57-16).

Several studies on outcomes after RN for localized RCC have now demonstrated that the risk of postoperative recurrent malignant disease is stage dependent, and surveillance protocols should reflect this (Stephenson et al, 2004; Skolarikos et al, 2007). A recent American Urological Association (AUA) Guidelines Panel reviewed this literature and provided recommendations for the surveillance of patients after renal surgery for localized renal RCC (Donat et al, 2013). Table 57-12 outlines general surveillance considerations that apply to all patients managed for a localized renal mass, including the role of laboratory testing, longitudinal assessment of renal function, and specific indications for central nervous system or bone imaging. Table 57-13 provides stage-specific information for patients managed with surgical excision, particularly the indications for abdominal and thoracic imaging.

Partial Nephrectomy

Nephron-sparing surgery for the treatment of a renal tumor was first described by Czerny in 1890 (reviewed in Herr, 2005). However, high morbidity limited its application. In 1950, Vermooten suggested that peripheral encapsulated renal neoplasms could be excised locally while leaving a margin of normal parenchyma around the tumor. Interest in PN for RCC has subsequently been stimulated by advances in renal imaging, experience with renal vascular surgery for other conditions, improved methods of preventing ischemic renal damage, growing numbers of incidentally discovered low-stage RCCs, greater appreciation of the deleterious effects of CKD, and encouraging long-term survival in patients undergoing this form of treatment (Uzzo and Novick, 2001). Nephron-sparing surgery entails complete local resection of

Figure 57-16. Laparoscopic radical nephrectomy (a retroperitoneal approach is illustrated) provides excellent oncologic outcomes and rapid recovery but predisposes patients to chronic kidney disease and potential cardiovascular risks and increased mortality rates. Nephron-sparing approaches should be prioritized whenever reasonable. (Reprinted with permission, Cleveland Clinic Center for Medical Art and Photography, © 2013. All Rights Reserved.)

the tumor while leaving the largest possible amount of normal functioning parenchyma in the involved kidney (Fig. 57-17).

Accepted indications for PN traditionally included situations in which RN would render the patient anephric or at high risk for ultimate need of dialysis (Licht et al, 1994; Russo et al, 2008; Campbell et al, 2009). This encompassed patients with bilateral RCC or RCC involving a solitary functioning kidney. A solitary functioning kidney may be the result of unilateral renal agenesis, prior removal of the contralateral kidney, or irreversible impairment of contralateral renal function by a benign disorder. Another traditional relative indication for PN was represented by patients with unilateral RCC and a functioning opposite kidney affected by a condition that might threaten its future function, such as renal artery stenosis (Campbell et al, 1993; Hafez et al, 2000), hydronephrosis, chronic pyelonephritis, ureteral reflux, calculus disease, or systemic diseases such as diabetes and nephrosclerosis (Uzzo and Novick, 2001; Campbell et al, 2009; Novick, 2009).

In patients with bilateral synchronous RCC, the general approach has been to preserve as much functioning renal tissue as possible. This entails performing bilateral PNs when feasible, usually as staged procedures, particularly if the tumors are relatively large. When a locally extensive tumor on one side precludes nephron-sparing surgery, an RN is performed on the more involved side along with a contralateral PN (Booth et al, 2008; Nguyen et al, 2008a; Rothman et al, 2008). Margin width appears to be immaterial as long as the final margins are negative; this is particularly relevant when the tumor is located within the hilum and preservation of renal function is at a premium (Li et al, 2008; Yossef-owitch et al, 2008; Campbell et al, 2009; Bensalah et al, 2010; Bernhard et al, 2010; Sundaram et al, 2011; Marszalek et al, 2012).

Patients with RCC involving a functionally or anatomically solitary kidney must be advised about the potential need for temporary or permanent dialysis postoperatively. In the series by

Fergany and colleagues (2006), 3.5% of patients with a solitary kidney managed with PN required temporary dialysis, and 18 of 400 patients (4.5%) eventually progressed to end-stage renal failure at a mean of 3.6 years after surgery. Many of these patients also had preexisting CKD before surgery, and in some instances only a small remnant kidney could be preserved because of large tumor size and anatomic considerations. Similarly, Ghavamian and colleagues (2002) reported a 12.7% incidence of acute renal failure when operating on a solitary kidney, with 15.9% of patients developing proteinuria and 12.7% experiencing severe CKD on a long-term basis. A functioning renal remnant of at least 20% to 30% of one kidney is necessary to avoid end-stage renal failure, although this presumes good functional status of the remaining parenchyma (Uzzo and Novick, 2001). Overall preservation of renal function is thus achieved in the great majority of patients with PN, even in patients with traditional imperative indications (Nguyen et al, 2008a). Local recurrence after PN for imperative indications traditionally ranged from 3% to 5%, because many of these cases were particularly challenging owing to hilar tumor location, the need to minimize the amount of excised functional parenchyma, tumor multifocality, or other complexities (Uzzo and Novick, 2001; Nguyen et al, 2008a).

In some patients with absolute indications, PN may not be anatomically feasible and radical surgery followed by dialysis may need to be considered. Renal transplantation may be an option for some of these patients after an appropriate cancer-free interval. An alternative approach is a trial of tyrosine kinase inhibitor therapy in an effort to downsize the tumor and enable PN, which can be successful in some instances (Thomas et al, 2009a; Gorin et al, 2012a; Kroon et al, 2013). Renal mass biopsy should be performed because clear cell histology appears to respond best to this approach (Rini et al, 2012). Meticulous surgical technique is paramount because the tyrosine kinase inhibitors can

TABLE 57-12 Surveillance for Clinically Localized Renal Neoplasms: General Considerations

FOLLOW-UP MEASURE	RECOMMENDATION
Physical examination and history	History and physical examination directed at detecting signs and symptoms of metastatic spread or local progression.
Laboratory testing	Basic laboratory testing, including BUN/creatinine, urinalysis, and eGFR, for all patients. Progressive renal insufficiency should prompt nephrology referral. CBC, LDH, LFTs, alkaline phosphatase, and serum calcium per discretion of the physician.
Central nervous system imaging	Acute neurologic signs should lead to prompt neurologic cross-sectional imaging of the head or spine based on localized symptoms.
Bone scan	Elevated alkaline phosphatase, clinical symptoms such as bone pain, and/or radiographic findings suggestive of a bony neoplasm should prompt a bone scan. Bone scan should not be performed in the absence of these signs and symptoms.

BUN, blood urea nitrogen; CBC, complete blood count; eGFR, estimated glomerular filtration rate; LDH, lactate dehydrogenase; LFTs, liver function tests.

Modified from Donat SM, Diaz M, Bishoff JT, et al. Follow-up for clinically localized renal neoplasms: AUA guideline. *J Urol* 2013;190:407–16.

impair tissue healing, and these agents should be withheld for at least a few half-lives before and after PN (Thomas et al, 2009b; Hellenthal et al, 2010; Chapin et al, 2011).

PN is now standard of care for the management of small renal masses (clinical T1a) in the presence of a normal contralateral kidney, presuming that the mass is amenable to this approach (Huang et al, 2009; Lane et al, 2009b). A robust literature demonstrates equivalent oncologic outcomes with PN when compared with RN in appropriately selected patients, and the renal functional outcomes tilt the balance in favor of nephron-sparing approaches whenever feasible (Russo and Huang, 2008; Thompson et al, 2008; Huang et al, 2009; Van Poppel et al, 2011a). Prior experience with “elective” PN for T1a RCC demonstrated local recurrence rates of 1% to 2%, and overall cancer-free survival well over 90% (Campbell et al, 2009). The morbidity of PN has also decreased substantially in recent years in experienced hands (Thompson et al, 2005c; Joudi et al, 2007; Patard et al, 2007). The majority of local recurrences observed after PN are most likely a manifestation of undetected microscopic multifocal RCC in the renal remnant—most are found distant from the previous tumor bed. Concern about local recurrence after elective PN is counterbalanced by a 1% to 2% incidence of contralateral RCC on longitudinal surveillance, in which case RN would have left the patient with tumor in a solitary kidney (Nguyen et al, 2008a; Russo et al, 2008).

Evaluation of patients with RCC for PN should include preoperative testing to exclude locally extensive or metastatic disease and additional specific renal imaging to delineate the relationship of the tumor to the intrarenal vascular supply and collecting system. Three-dimensional volume-rendered CT (or MRI) is now established as a noninvasive imaging modality that can accurately depict the renal parenchymal and vascular anatomy in a format

TABLE 57-13 Surveillance after Radical or Partial Nephrectomy*

FOLLOW-UP MEASURE	RECOMMENDATION
LOW-RISK PATIENTS (pT1N0MX)	
Abdominal imaging	Partial Nephrectomy: Obtain a baseline abdominal scan (CT or MRI) within 3-12 months following surgery. If the initial postoperative scan is negative, abdominal imaging (US, CT, or MRI) may be performed yearly for 3 years based on individual risk factors. Radical Nephrectomy: Patients should undergo abdominal imaging (US, CT, or MRI) within 3-12 months following surgery. If the initial postoperative imaging is negative, abdominal imaging beyond 12 months may be performed at the discretion of the clinician.
Chest imaging	Partial and Radical Nephrectomy: Obtain a yearly CXR for 3 years and only as clinically indicated beyond that time period.
MODERATE- TO HIGH-RISK PATIENTS (pT2-4N0MX OR pT[ANY]N1MX): PARTIAL OR RADICAL NEPHRECTOMY	
Abdominal imaging	A baseline abdominal scan (CT or MRI) within 3-6 months following surgery with continued imaging (US, CT, or MRI) every 6 months for at least 3 years and annually thereafter to year 5. Imaging beyond 5 years may be performed at the discretion of the clinician. Perform site-specific imaging as symptoms warrant.
Chest imaging	Obtain a baseline chest scan (CT) within 3-6 months following surgery with continued imaging (CXR or CT) every 6 months for at least 3 years and annually thereafter to year 5. Imaging beyond 5 years is optional and should be based on individual patient characteristics and tumor risk factors.

*Please also refer to Table 57-12 for general considerations related to surveillance.

CT, computed tomography; CXR, chest x-ray; MRI, magnetic resonance imaging; US, ultrasound.

familiar to urologic surgeons (Uzzo et al, 2000; Simmons et al, 2007; Novick, 2009). This study integrates essential information from arteriography, venography, excretory urography, and conventional two-dimensional CT into a single imaging modality and obviates the need for more invasive renal imaging. The surgical techniques for performing nephron-sparing surgery in patients with RCC are reviewed in Chapters 60 and 61.

One of the largest reported studies of nephron-sparing surgery is from the Cleveland Clinic and reviewed the results of PN for the treatment of localized, sporadic RCC in 485 patients (Hafez et al, 1999). The mean postoperative follow-up was 4 years, and overall and cancer-specific 5-year survival rates

Figure 57-17. Essential steps in partial nephrectomy as illustrated with open approach. A, Temporary occlusion of the vascular pedicle and excision of the tumor with a rim of normal parenchyma. B, Closure of the collecting system and ligation of transected vessels. C, Capsular reconstruction. (Reprinted with permission, Cleveland Clinic Center for Medical Art and Photography, © 2007-9. for patients in this series were 81% and 92%, respectively. Recurrent RCC developed postoperatively in 44 patients (9%), comprising 16 (3.2%) with local recurrence in the remnant kidney and 28 (5.8%) with metastatic disease. In another study from the Cleveland Clinic, long-term results of nephron-sparing surgery were reviewed in 107 patients with localized sporadic RCC treated before 1988 who were followed for a minimum of 10 years or until death (Fergany et al, 2000). Cancer-specific survival was 88% at 5 years and 73% at 10 years. Long-term renal function was preserved in 100 patients (93%). These results are particularly impressive given the patient population in that era, almost all of whom underwent PN for imperative indications. Ten-year follow-up was also provided by Herr (1999), who reported that 97% of patients remained cancer free after PN in the setting of a normal contralateral kidney, a more select population of patients. These data confirm that nephron-sparing surgery provides effective long-term therapy for patients with localized RCC and can preserve renal function in the overwhelming majority (Nguyen et al, 2008a; Ching et al, 2013).

A more recent trend has been to perform PN by minimally invasive approaches, with several series reporting encouraging results (Gill et al, 2002, 2003, 2006, 2007, 2010b; Permpongkosol et al, 2006a; Gill, 2012; Lane et al, 2013c). Whether pure laparoscopic or facilitated by robotic assistance (see Chapter 61), it is now possible to replicate the essential steps of the open surgical technique for many tumors, including occlusion of the renal vasculature, excision of the tumor with a rim of normal parenchyma, and intracorporeal suturing to close the collecting system and repair the capsular defect (Desai et al, 2003). Margin status and oncologic outcomes associated with laparoscopic or robotic PN appear to be equivalent to open PN in experienced hands, presuming sensible patient selection (Lane and Gill, 2007). The RENAL (Radius, Endophytic vs. exophytic, Nearness to collecting system, Anterior/posterior, Location relative to polar lines) and other nephrometry scoring systems allow for assessment of the complexity of the tumor and have facilitated comparison of evolving surgical techniques for PN in this era (Kutikov and Uzzo, 2009; Simmons et al, 2010, 2012). Early to intermediate experience with laparoscopic PN demonstrated increased rates of urologic complications such as postoperative hemorrhage and need for subsequent surgery despite selection for less complex tumors

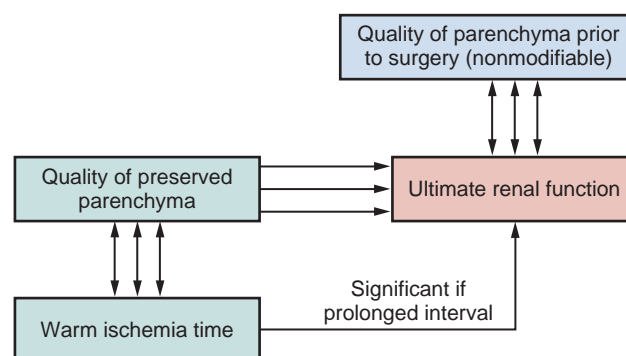

Figure 57-18. Determinants of ultimate renal function after partial nephrectomy. The quality and quantity of preserved parenchyma are the main determinants of renal function after partial nephrectomy, with ischemic injury playing a secondary role as long as limited warm ischemia or hypothermia is utilized. Prolonged warm ischemia, however, can lead to irreversible loss of nephron function.

in healthier patients (Gill et al, 2007). However, further experience and more prevalent utilization of robotic assistance have led to substantially reduced morbidity, and these minimally invasive approaches are now well established in our armamentarium for PN, presuming sensible patient selection based on tumor complexity and surgeon experience (Turna et al, 2009; Gill et al, 2010b; Dulabon et al, 2011; Kaouk et al, 2011, 2012; Mullins et al, 2012; Lane et al, 2013c).

One ongoing controversy in the field relates to the determinants of renal function after PN, which has important implications with respect to surgical technique. One of the main objectives of PN is to preserve as much renal function as possible, and the factors that can influence ultimate renal function include the quality of the parenchyma prior to surgery, the quantity of vascularized parenchyma that can be preserved, and potential deleterious effects of ischemia (Fig. 57-18). The quality of the parenchyma is for the most part nonmodifiable, essentially setting the baseline of renal function that would persist if no intervention was performed.

Most studies that have incorporated the other two, potentially modifiable, factors into multivariable analysis suggest that the number of preserved nephrons is the primary factor determining renal function after PN, while ischemic injury plays a secondary role (Song et al, 2009; Lane et al, 2011; Simmons et al, 2011; Weight and Thompson, 2012). Stated another way, as long as the warm ischemic interval is limited (<25 minutes) or hypothermia is applied, most preserved nephrons will recover their function (Campbell, 2012; Thompson et al, 2012; Mir et al, 2013). Precise excision of the tumor with a small rim of normal parenchyma along with careful reconstruction of the kidney to minimize devascularization is of paramount importance and can be facilitated by a short ischemic interval to allow for a bloodless field. Hypothermia should be considered for more complex cases or whenever a prolonged ischemic interval is anticipated, particularly for patients with a solitary kidney or preexisting CKD. However, other techniques and perspectives, such as the concept of segmental arterial clamping (Gill et al, 2011, 2012; Shao et al, 2011), have shown promise and further investigation will be required to address ongoing controversies in this field (see Chapter 61).

Surveillance of patients after PN, similar to RN, can be tailored to pathologic tumor stage; the basic recommendations are detailed in Tables 57-12 and 57-13. These protocols should help minimize costs, radiographic exposure, and patient inconvenience while still allowing for detection of most clinically relevant recurrences (Donat et al, 2013).

Patients who undergo nephron-sparing surgery for RCC may be left with a relatively small amount of renal tissue and are at risk for development of long-term renal functional impairment from hyperfiltration renal injury (Modlin and Novick, 2001; Abdi et al, 2003; Lane et al, 2009b; Novick, 2009). In a study of 14 patients observed for up to 17 years after PN in a solitary kidney, patients with more than 50% reduction in overall renal mass were found to be at increased risk for development of proteinuria, focal segmental glomerulosclerosis, and progressive renal failure (Novick et al, 1990). The development of proteinuria correlated directly with the length of follow-up and inversely with the amount of remaining renal tissue. Renal biopsy revealed focal segmental glomerulosclerosis in several patients with severe proteinuria (Fig. 57-19). These findings mirror those observed in experimental animal models of partial renal ablation (Brenner,

1983). Because proteinuria is the initial manifestation of this phenomenon, a 24-hour urinary protein measurement should be obtained yearly in patients with a solitary remnant kidney to screen for hyperfiltration nephropathy. Efforts to prevent or to ameliorate the damaging effects of renal hyperfiltration have focused on dietary and pharmacologic interventions, primarily the use of angiotensin-converting enzyme inhibitors combined with a low-protein diet (Goldfarb, 1995; Novick and Schreiber, 1995).

Thermal Ablative Therapies

Thermal ablative therapies, including renal cryosurgery and radiofrequency ablation (RFA), have emerged as alternative nephron-sparing treatments for patients with localized RCC (Murphy and Gill, 2001; Sterrett et al, 2008). Both can be administered percutaneously or through laparoscopic exposure and thus offer the potential for reduced morbidity and more rapid recovery (Johnson et al, 2004; Sterrett et al, 2008). Effect on renal function is typically limited, and these modalities appear to be reasonable choices for select patients with tumor in a solitary kidney, although PN remains the optimal choice in this circumstance (Weisbrod et al, 2010; Altunrende et al, 2011). In general, long-term efficacy of TA is not as well established when compared to surgical excision, and current data suggest that the local recurrence rates are somewhat higher than those reported for traditional surgical approaches (Kunkle et al, 2008; Campbell et al, 2009). Another concern has been the lack of accurate histologic and pathologic staging associated with these modalities, because the treated lesion is left in situ.

The ideal candidates for TA procedures may be patients with advanced age or significant comorbidities who prefer a proactive approach but are not optimal candidates for conventional surgery, patients with local recurrence after previous nephron-sparing surgery, and patients with hereditary renal cancer who present with multifocal lesions for which multiple PNs might be cumbersome (Kunkle et al, 2008). Patient preference must also be considered, and some patients not fitting these criteria may also select TA, a decision that can be supported as long as balanced counseling about the current status of these modalities has been provided (Matin and Ahrar, 2009; Faddegon and Cadeddu,

Figure 57-19. A, Ten years after partial nephrectomy for a large tumor in a solitary left kidney, an intravenous pyelogram shows function of small renal remnant. The patient had developed nephrotic syndrome at this time. B, Renal biopsy specimen shows focal segmental glomerulosclerosis indicative of hyperfiltration nephropathy.

2012). Finally, tumor size is also an important factor in patient selection because the current technology does not allow for reliable treatment of lesions larger than 4.0 cm in diameter, and success rates appear to be highest for tumors smaller than 2.5 to 3.0 cm (del Cura et al, 2010; Tracy et al, 2010; Tanagho et al, 2012; Atwell et al, 2013).

Experience with renal cryosurgery predates that of RFA and has been more extensive (Sterrett et al, 2008). Established prerequisites for successful cryosurgery include rapid freezing, gradual thawing, and a repetition of the freeze-thaw cycle. The mechanism underlying tissue cryodestruction is thought to involve immediate membrane and cellular damage followed by microcirculatory failure (Stein and Kaouk, 2007). Intracellular ice irreversibly disrupts cell organelles and the cell membrane, a lethal event. Delayed microcirculatory failure occurs during the slow thaw phase of the freeze-thaw cycle, leading to circulation arrest and cellular anoxia. Cells that survive the initial cryogenic assault are destroyed by this secondary insult of ischemia. Repetition of the rapid freeze-slow thaw cycle potentiates the damage (Hinshaw and Lee, 2004).

Further work defined treatment parameters required to bring this treatment into the clinical domain. Chosy and colleagues (1996) demonstrated that complete and reliable tissue necrosis could be consistently achieved only at temperatures of -19.4°C or lower. Campbell and coworkers (1998) confirmed that the target lethal temperature of -20°C was achieved at a distance of 3.1 mm inside the leading edge of the iceball as visualized by real-time ultrasonography. Thus, to ensure complete cell kill, the iceball must extend well beyond the visible margins of the targeted tumor. In practice, we routinely extend the iceball approximately 1 cm beyond the edge of the tumor, as determined by real-time imaging (Gill et al, 1998). The availability of sophisticated and reliable ultrasonography and the introduction of finer cryoprobes that allow more accurate and less traumatic probe placement have contributed to even greater interest in visceral cryosurgery (Sterrett et al, 2008).

Clinical experience and follow-up of patients after renal cryoablative therapy suggests successful local control in about 90% of patients, although many studies provide limited, and often incomplete, follow-up (Gill et al, 2005; Stein and Kaouk, 2007; Campbell and Palese, 2011; Klatte et al, 2011; Guillotreau et al, 2012). Diagnosis of local recurrence after TA can be challenging because evolving fibrosis within the tumor bed can be difficult to differentiate from residual cancer. In general, central or nodular enhancement within the tumor bed on extended follow-up has been considered diagnostic of local recurrence, and the clinical experience with cryoablation has thus far supported this (Bolte et al, 2006; Weight et al, 2008). However, only a minority of studies have incorporated routine post-therapy biopsies to provide histologic confirmation of oncologic status (Gill et al, 2000; Weight et al, 2008). Other findings that suggest local recurrence include a progressive increase in size of an ablated neoplasm, new nodularity in or around the treated zone, failure of the treated lesion to regress over time, or satellite or port site lesions (Donat et al, 2013). If these features are found, biopsy and possible retreatment should be considered. The AUA guidelines for surveillance after TA are outlined in Tables 57-12 and 57-14.

Reported rates of local recurrence in some of the TA series may represent underestimates because about 20% of small renal masses are benign rather than RCC, and a pretreatment biopsy, although strongly advocated in the field, has not been routinely performed in many series (Heilbrun et al, 2007; Sterrett et al, 2008). In general, the literature regarding TA is still notable for a variety of deficiencies, including limited follow-up in the great majority of studies and poor quality of reporting (Campbell and Palese, 2011; Kang et al, 2012). More mature data are now available in a limited number of studies, supporting encouraging outcomes for smaller tumors, particularly those less than 3.0 cm in diameter, yet the cumulative experience continues to suggest that local control after cryoablative therapy remains suboptimal

TABLE 57-14 Surveillance after Renal Ablation*

FOLLOW-UP MEASURE	RECOMMENDATION
Diagnostic biopsy	Patients should undergo a pretreatment diagnostic biopsy.
Abdominal scan	Cross-sectional scanning (CT or MRI) with and without IV contrast unless otherwise contraindicated at 3 and 6 months following ablative therapy, with continued scanning annually thereafter for 5 years. Imaging beyond 5 years is optional based on individual risk factors.
Chest imaging	Patients who have either biopsy-proven low-risk renal cell carcinoma, [†] oncocytoma, a tumor with oncocytic features, nondiagnostic biopsies, or no prior biopsy should undergo annual CXR for 5 years. Imaging (CXR or CT) beyond 5 years is optional based on individual patient risk factors and the determination of treatment success. Radiographic scanning is not recommended with pathologic confirmation of benign disease at or before treatment and post-treatment radiographic confirmation of treatment success and no evidence of treatment-related complications.
Repeat biopsy	New enhancement, a progressive increase in size of an ablated neoplasm with or without contrast enhancement, new nodularity in or around the treated zone, failure of the treated lesion to regress over time, or satellite or port site lesions should prompt a repeat lesion biopsy. Observation, repeat treatment, and surgical intervention should be discussed for recurrence.

*Please also refer to Table 57-12 for general considerations related to surveillance.

[†]Based on the definitions adopted for this guidelines process, thermal ablation should be restricted primarily to low-risk patients. In more general terms, any patient with renal cell carcinoma managed with thermal ablation should undergo annual CXR for 5 years.

CT, computed tomography; CXR, chest x-ray; IV, intravenous; MRI, magnetic resonance imaging.

Modified from Donat SM, Diaz M, Bishoff JT, et al. Follow-up for clinically localized renal neoplasms: AUA guideline. J Urol 2013;190:407–16.

when compared to surgical excision (Kunkle et al, 2008; Guillotreau et al, 2012). For instance, in the series from Aron and colleagues (2010), the local recurrence rate at 5 years was 9%, and in the series from Lusch and colleagues (2013) it was approximately 8%. This can be contrasted with 5-year local recurrence rates of about 1% to 2% for surgical excision for analogous small renal masses (Campbell et al, 2009).

Other concerns with cryoablation, and TA in general, relate to surgical salvage and potential morbidity. Most local recurrences can be salvaged with repeat ablation, although some patients with progressive disease eventually require conventional surgery. Nguyen and colleagues (2008b) have shown that PN and minimally invasive approaches are occasionally precluded in this

setting because of the extensive fibrotic reaction induced by TA. This reaction appears to be more significant after cryoablation than after RFA, although the precise reasons for this are unclear at present (Kowalczyk et al, 2009). Complications associated with cryoablation can include renal fracture, hemorrhage, adjacent organ injury, ileus, and wound infection, although major morbidity is decidedly uncommon (Sidana et al, 2010; Tsivian et al, 2010). As expected, the incidence of treatment failure or complications after TA correlates with tumor size and complexity, as estimated by the RENAL scoring system (Schmit et al, 2013).

The experience with RFA has been more variable, likely related to surgeon experience, the availability of different platforms that can be accessed to perform this procedure, and inability to monitor treatment progress as stringently as cryoablation (Sterrett et al, 2008). Application of high-frequency electrical current by RFA induces excitation of ions, frictional forces, and heat, which in turn cause denaturation of intracellular proteins and melting of cellular membranes, a lethal sequence of events. These effects are observed at tissue temperatures above 41°C but increase directly with increasing temperature and duration of treatment (Sterrett et al, 2008). Temperatures in excess of 100°C are typically obtained at the tips of the probes, and thermosensors can be used to monitor progress during active treatment. Temperature dissipates at points more distant from the probe tip, and multiple probes or types are typically required to achieve adequate heating of the entire region of interest (Murphy and Gill, 2001). One disadvantage of RFA is that the treatment effect is potentially more difficult to monitor in real time—there is no true “iceball equivalent” (Zelkovic and Resnick, 2003). Rather, treatment is typically based on empirical results from previous probe alignments, supplemented by data from thermoprobes, and this allows a fairly predictable target zone of up to 4.0 cm to be treated in most cases. Maximal tumor size that can be reliably treated would of necessity be smaller than this, given the need to extend the treatment zone beyond all edges of the tumor.

Local control after RFA is difficult to determine owing to a number of complexities, although most estimate that this will be 80% to 90% on a longitudinal basis using strict definitions of local recurrence (Kunkle et al, 2008; Campbell et al, 2009). Loss of enhancement on cross-sectional imaging within the lesion has generally been accepted as an indicator of success, although this has been challenged. Weight and colleagues (2008) reported 6 patients with no enhancement on MRI performed 6 months after RFA who were found to have apparently viable cancer cells on biopsy of the tumor bed. The issue of potential false-negative and false-positive imaging findings after TA remains a concern, although such events appear to be relatively uncommon (Matin, 2010). More strict definitions of local control after TA were recently advocated by an AUA guidelines panel and are reviewed in Table 57-14 (Donat et al, 2013).

The technology for RFA continues to improve, and most contemporary series report relatively low rates of local recurrence, although some patients require repeat treatments to achieve local control, which is an infrequent event with cryoablation and rarely required with conventional surgical treatments for localized RCC (Sterrett et al, 2008). In the series from Tracy and colleagues (2010) there were seven treatment failures and nine other local recurrences among 179 patients with biopsy proven RCC during median follow-up of 27 months. Using strict criteria, local control was achieved in 91% of patients in this series; however, many of the patients with local recurrence were potentially salvaged with repeat ablation or surgical excision, and overall cancer-specific survival remained high. Longer follow-up will be required to more fully evaluate outcomes in this and other series in the RFA literature. Some RFA series report even more encouraging results, particularly for tumors less than 3.0 cm diameter (Atwell et al, 2013), whereas others have reported 5-year local recurrence rates as high as 39% (Samarasekera et al, 2013).

Complications from RFA are uncommon but have included acute renal failure, stricture of the ureteropelvic junction,

necrotizing pancreatitis, and lumbar radiculopathy, so careful and judicious selection of patients is essential (Sterrett et al, 2008). Direct comparison with cryoablation is inevitable but perhaps unfair because RFA is earlier in its development and recent reports suggest great promise (Sterrett et al, 2008; Atwell et al, 2013).

Other exciting new technologies, such as high-intensity focused ultrasound (HIFU) and frameless, image-guided radio-surgical treatments (CyberKnife), are also under development and may allow extracorporeal treatment of small renal tumors in the future (Ponsky et al, 2007; Haber et al, 2010; Kroeze et al, 2012). However, at present cell kill with these modalities is not sufficiently reliable and they are best considered developmental (Castle et al, 2011).

Active Surveillance

There was once relatively little information about the growth rate of RCC because almost all renal tumors were excised shortly after detection based on prior paradigms of management (Jewett and Zuniga, 2008; Graversen et al, 2011; Lane et al, 2012). The incidental discovery of many small RCCs in asymptomatic elderly patients or those of poor surgical risk has provided the opportunity to observe the growth rate of these tumors in patients who are unable or unwilling to undergo surgery (Abouassaly et al, 2008; Chen and Uzzo, 2009; Crispen et al, 2009; Rosales et al, 2010; Mason et al, 2011). Bosniak and associates (1995) reported one of the first and largest series of AS that included 72 small (<3.5 cm) renal tumors in 68 patients who were observed with serial imaging studies for intervals ranging from 2 to 10 years (mean, 3.3 years). On CT these were well-margined, homogeneous, solid, enhancing tumors consistent with RCC. During the period of observation these tumors grew at slow and variable rates of up to 1.1 cm per year, with a median growth rate of 0.36 cm per year. In 32 patients whose tumors grew to larger than 3 cm, surgical excision was performed; all the excised tumors proved to be stage pT1a RCCs, and the majority were grade 1 tumors. Significantly, none of the patients developed metastasis during the period of surveillance.

Subsequent series from several institutions have confirmed that many small renal masses will grow relatively slowly (median growth rate 0.12 to 0.34 cm/yr) and with a relatively low rate of metastasis (1.2% to 2.0% during 2 to 4 years of follow-up), suggesting that this may be a reasonable management strategy in carefully selected patients who are not candidates for conventional surgery or thermal ablative approaches (Campbell et al, 2009; Graversen et al, 2011; Jewett et al, 2011; Smaldone et al, 2012). However, a critical review of this literature is required to recognize the potential limitations of these studies (Campbell et al, 2009). First, most AS series have included only relatively small, well-margined, and homogeneous renal masses, reflecting strong selection bias. A substantial proportion (20% or more) of these tumors may have been benign—biopsy was only performed in a minority of patients in these series. In addition, follow-up in most series is limited to 2 to 3 years, and in some cases the growth rate was calculated backward by obtaining old films for which the lesion of interest was either previously missed or dismissed, introducing a possible ascertainment bias (Jewett and Zuniga, 2008; Crispen et al, 2012). Finally, in most of these series there is a subpopulation of patients with rapidly growing tumors that appear to have more aggressive characteristics. For instance, in the series from Volpe and colleagues (2004), 25% of the masses doubled in volume in 12 months and 22% reached a diameter of 4 cm, triggering surgical intervention. Similarly, Sowers and Siemens (2004) reported 9 tumors with mean growth rate of 1.43 cm per year, representing a substantial proportion of their patients. Salvage of patients with metastatic RCC is unlikely, and in some patients the window of opportunity for nephron-sparing surgery may be lost.

Nevertheless, these studies suggest that patients with small, solid, enhancing, well-margined, homogeneous renal lesions,

who are elderly or poor surgical risks, can safely be managed with observation and serial renal imaging at 6-month or 1-year intervals (Jewett and Zuniga, 2008; Campbell et al, 2009; Chen and Uzzo, 2009; Kutikov et al, 2012). In this population, the risk of competing noncancer causes of death and the risk of intervention will most often outweigh the risk of RCC progression (Hollingsworth et al, 2007). In fact, recent data indicate that active treatment of small renal masses in elderly patients (>75 years of age) may not confer a measurable survival benefit over AS, further supporting a conservative approach in many of these patients (Lane et al, 2010). Prospective data and studies with more prolonged follow-up are now becoming available, and in general are supportive of AS in appropriately selected patients (Haramis et al, 2011; Jewett et al, 2011). The AUA guidelines provide recommendations for follow-up of patients on AS, as outlined in Tables 57-12 and 57-15, including consideration for renal mass biopsy to stratify oncologic risk.

In general, AS is not appropriate for patients with larger (>3 to 4 cm), poorly marginated, or nonhomogeneous solid renal lesions, or when biopsy indicates a potentially aggressive RCC, except in patients with limited life expectancy (Remzi et al, 2006; Kunkle et al, 2007). AS is also not advisable in younger, otherwise healthy, patients with small, solid tumors that have radiographic

characteristics consistent with RCC (Campbell et al, 2009; Lane et al, 2012). Even if these lesions are smaller than 3 cm, the current data indicate that most will grow and eventually reach a size at which metastasis becomes a possibility. Unfortunately, growth rates on observation do not allow for reliable differentiation of benign versus malignant histology (Siu et al, 2007; Crispen et al, 2008b; Kawaguchi et al, 2011). Therefore, in this setting, it is more appropriate to consider treating the tumor by surgical excision or TA when it is small, clearly localized, and still amenable to nephron-sparing approaches (Van Poppel and Joniau, 2007; Campbell et al, 2009; Chen and Uzzo, 2009).

Clinical T1 Renal Mass: Algorithm for Management

Acknowledging substantial controversy with respect to the management of small renal masses, with some current practices discordant with what the literature supports, the AUA Practice Guidelines Committee organized a panel to review this topic (Campbell et al, 2009). This process included a systematic meta-analysis of the literature, and the final document was vetted through an extensive peer review process. As expected, the database for open surgical techniques was most substantial and mature (Table 57-16). In contrast, follow-up for many of the other modalities was rather limited. Review of the data demonstrates strong selection biases, with RN procedures used to treat larger tumors, and AS and TA primarily applied to an older population of patients. There were almost no comparative studies; the overwhelming majority were retrospective and primarily observational. Other limitations of the data are detailed in the final document. The analysis revealed a small number of statistically significant comparisons of consequence for which confounding factors were unlikely to account for differences.

One such finding pertained to urologic complications, such as postoperative hemorrhage or urine leak, with PN procedures (laparoscopic and open) associated with the highest rates, likely reflecting the substantial technical challenges associated with these procedures (Table 57-17). This was thought to be a valid finding because PN procedures tended to be applied to younger patients and smaller tumors—patients who would be less likely to have such complications unless the complications were associated with procedural characteristics. A second significant result related to local recurrence, which was defined as any persistent or recurrent disease present in the treated kidney or ipsilateral renal fossa after initial treatment. This definition was adopted from standardized terminology developed by the International Working Group on Image-guided Tumor Ablation (Goldberg et al, 2005; Campbell et al, 2009). TA procedures had significantly higher rates of local recurrence when compared with all other treatment modalities (Table 57-18). This was also judged to be a valid finding, because these modalities were used to treat relatively small tumors and had short follow-up durations. In reality, it has been estimated that, when confounding factors such as length of follow-up are

TABLE 57-15 Active Surveillance: Imaging Recommendations*

FOLLOW-UP MEASURE	RECOMMENDATION
Percutaneous biopsy	Percutaneous biopsy may be considered prior to active surveillance.
Abdominal imaging	Cross-sectional scanning (CT or MRI) within 6 months of active surveillance initiation to establish a growth rate, with continued imaging (US, CT, or MRI) at least annually thereafter.
Chest imaging	Patients with biopsy-proven renal cell carcinoma or a tumor with oncocytic features on active surveillance should undergo annual CXR.

*Please also refer to Table 57-12 for general considerations related to surveillance.

taken into consideration, the local recurrence rates for cryoablation and RFA will be substantially higher than for surgical excision (Kunkle et al, 2008). Many such recurrences can be salvaged with repeat ablation, but when this is not possible, surgical salvage can be challenging (Kunkle et al, 2008; Nguyen et al, 2008b; Kowalczyk et al, 2009). Other ongoing concerns with TA were reviewed previously. Analyses of other survival end points, such as metastasis-free, cancer-specific, and overall survival, indicated that all such survival rates were relatively high across treatments, reflecting the limited biologic aggressiveness of most clinical T1 renal tumors. Given strong selection biases and highly variable follow-up differences across treatments, comparisons related to these outcomes were not informative (Campbell et al, 2009).

Final management recommendations were framed in terms of each treatment modality's utility in the context of four index patients defined by tumor size (T1a vs. T1b) and general health (Fig. 57-20). Index patient 1, a healthy patient with a clinical T1a renal mass, is the most commonly encountered scenario. PN is a standard for this patient, with RN an alternate standard that should be applied only when PN is not feasible. One of the main concepts that is emphasized by this guideline document relates to the status of **nephron-sparing approaches as an overriding principle for the management of small renal masses, presuming that adequate oncologic control can be achieved** (Campbell et al, 2009). TA and AS are both options for index patient 1, although there are substantial concerns about these management strategies in this healthy patient. Given the complexity of counseling with such divergent

options for management, the panel believed strongly that a urologist should be involved in this process. The ongoing controversies about the management of larger renal masses in the presence of a normal contralateral kidney, and the need for better quality data, namely prospective, randomized trials, in this domain were reviewed previously. The panel also strongly advocated research priority for renal mass biopsy with molecular profiling to improve the estimation of tumor aggressiveness and facilitate more rational patient selection in this field (Fig. 57-21).

Nephron-Sparing Surgery in von Hippel-Lindau Disease and Other Forms of Familial Renal Cell Carcinoma

RCC in von Hippel-Lindau disease differs from its sporadic counterpart in that the diagnosis is made at a young age and there are usually multiple bilateral renal tumors (Kim et al, 2010; Linehan and Ricketts, 2013). Although these are generally low-stage tumors, they are capable of progression to metastasis and represent a frequent cause of death in patients with von Hippel-Lindau disease. RCC in these patients is characterized histopathologically by both solid tumors and renal cysts that contain either frank carcinoma or a lining of hyperplastic clear cells representing incipient carcinoma (Fig. 57-22).

The surgical options in patients with bilateral RCC and von Hippel-Lindau disease are bilateral nephrectomy and renal replacement therapy or nephron-sparing approaches such as PN

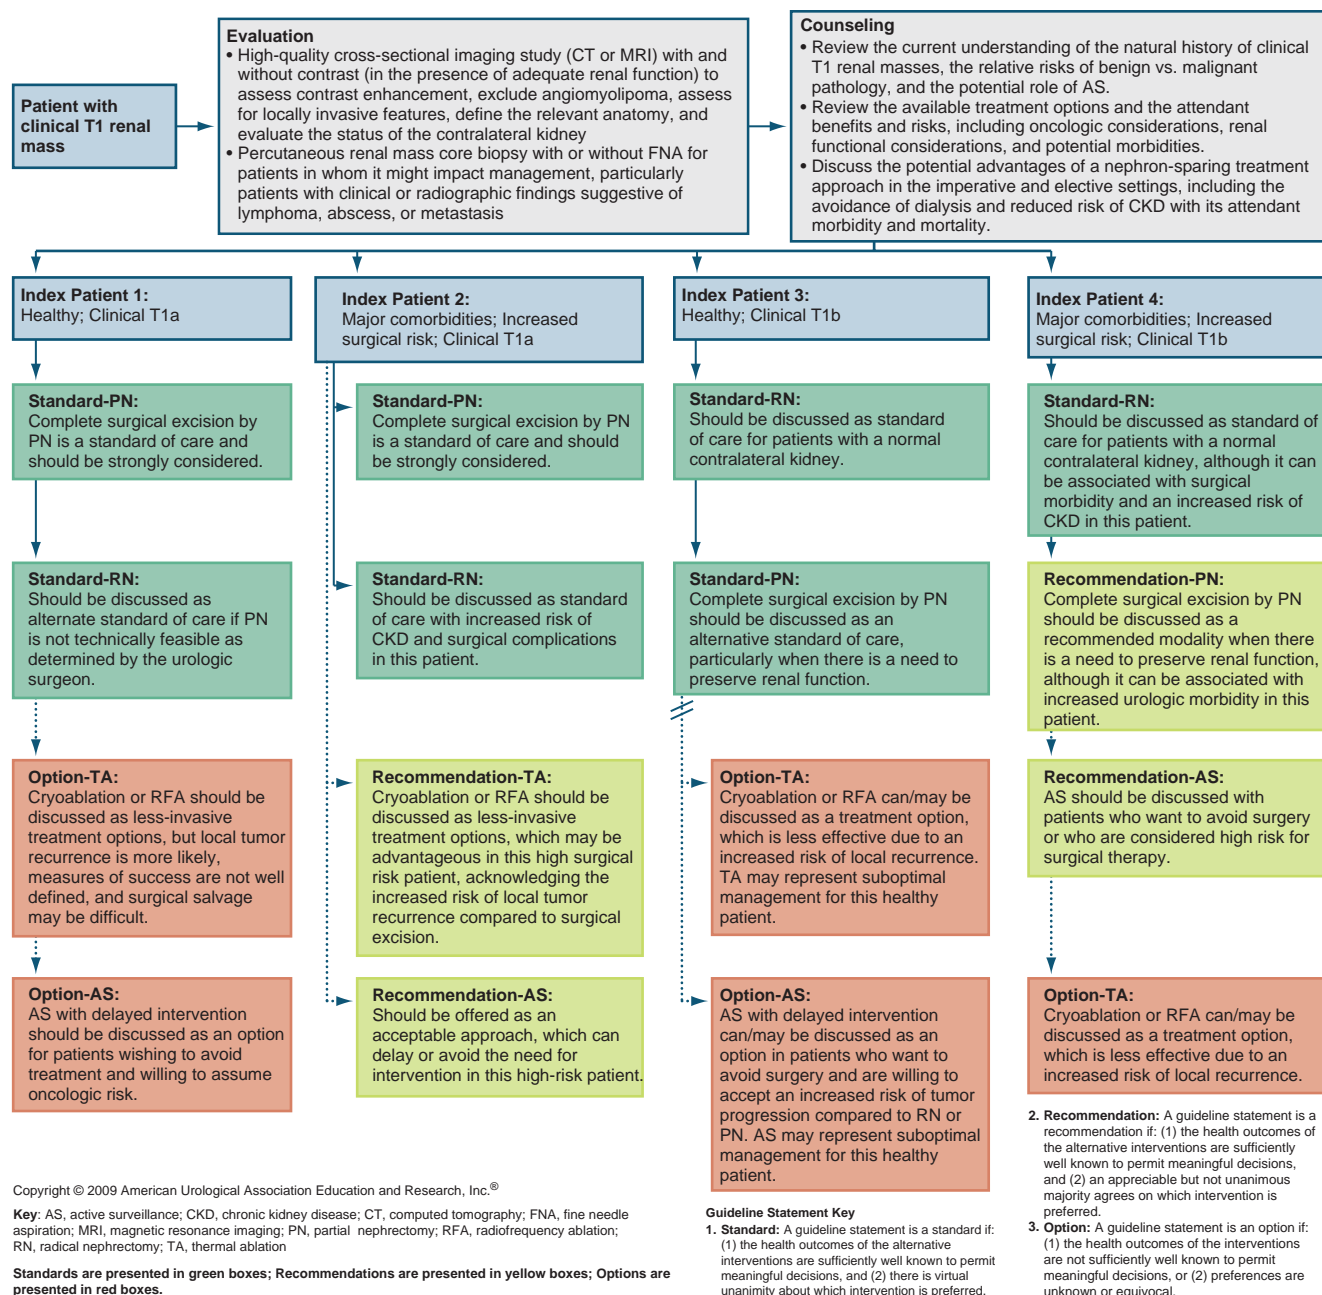

Figure 57-20. Algorithm for the evaluation, counseling, and management of the patient with a clinical T1 renal mass. (From American Urological Association Education and Research, Inc. Algorithm for management, <<https://www.auanet.org/common/pdf/education/clinical-guidance/Renal-Mass-Algorithm.pdf>>; 2009 [accessed 29.06.15].)

or TA to avoid end-stage renal disease. The general philosophy has been to pursue nephron-sparing strategies whenever possible, given the multifocal nature of the disease, even for centrally located tumors (Grubb et al, 2005; Shuch et al, 2012b; Linehan and Ricketts, 2013). For PN, an enucleative approach is often preferred rather than wide resection. Although early results of PN were promising, subsequent studies suggested a high incidence of post-operative tumor recurrence in the remaining portion of the kidney (Novick and Streem, 1992; Grubb et al, 2005). It is likely that most of these local recurrences were a manifestation of occult microscopic RCC that was not removed at the time of the original PN.

One multicenter study delineated the long-term outcomes after surgical treatment of localized RCC in 65 patients with von

Hippel-Lindau disease (Steinbach et al, 1995). RCC was present bilaterally and unilaterally in 54 and 11 patients, respectively. RN and PN were performed in 16 and 49 patients, respectively, and the mean postoperative follow-up interval was 68 months. The 5-year and 10-year cancer-specific survival rates for all patients were 95% and 77%, respectively. The corresponding rates for patients treated with PN were 100% and 81%, respectively. Survival free of local recurrence after PN was 71% at 5 years but only 15% at 10 years. Other studies confirm that patients with von Hippel-Lindau disease are at much higher risk for local recurrence than patients with sporadic RCC.

Duffy and colleagues (2004) at the National Cancer Institute have defined a 3-cm threshold for intervention in patients with

von Hippel-Lindau disease. In their series, a total of 108 patients with von Hippel-Lindau disease and solid renal tumors smaller than 3 cm were observed and none developed metastatic disease during mean follow-up of 58 months. In contrast, metastases developed in 20 of 73 patients (27.4%) with tumors larger than 3 cm and the frequency of metastases increased with increasing tumor size. A 3-cm cut point has thus been proposed to reduce the number of surgical interventions, to optimize renal function, and to minimize the risk of metastatic disease. This recommendation also applies to patients with HPRCC and Birt-Hogg-Dubé syndromes (Shuch et al, 2012b). However, HLRCC and SDH-RCC are exceptions in that tumors in these syndromes are typically more aggressive and should be managed accordingly, even when less than 3 cm (Shuch et al, 2012b).

Taken together, these studies suggest that PN can provide effective initial treatment of patients with RCC and von Hippel-Lindau disease but should be withheld until tumor size reaches or eclipses 3.0 cm. In recent years, TA has been used more frequently in this patient population as an alternative nephron-sparing approach (Matin et al, 2008; Park and Kim, 2010; Joly et al, 2011). After initial management, patients with von Hippel-Lindau disease must be observed closely because most will eventually develop locally recurrent RCC with the concomitant need for repeat renal intervention (Grubb et al, 2005; Ploussard et al, 2007). In this setting, repeat PN can be challenging because of

postoperative fibrosis, and TA may be preferred to reclaim local control (Liu et al, 2010; Agochukwu et al, 2012; Shuch et al, 2012b). Targeted agents are now being investigated in an effort to slow disease progression in patients with this syndrome (Grubb et al, 2005; Shuch et al, 2012b). When removal of all renal tissue is necessary for oncologic reasons, renal transplantation can provide satisfactory replacement therapy for end-stage renal disease and appears to be safe despite the tumor diathesis (Goldfarb et al, 1997).

Comprehensive management of patients suspected of having familial RCC should also include genetic counseling and screening for other manifestations of the disease process (as discussed in the earlier section on familial RCC and molecular genetics) (Shuch et al, 2012b). For patients with von Hippel-Lindau disease, identification of pheochromocytoma or central nervous system hemangioblastoma is particularly important before surgical intervention for RCC (Linehan and Ricketts, 2013).

TREATMENT OF LOCALLY ADVANCED RENAL CELL CARCINOMA

Inferior Vena Caval Involvement

One of the unique features of RCC is its frequent pattern of growth intraluminally into the renal venous circulation, also known as **venous tumor thrombus**. This growth may extend into the IVC with cephalad migration as far as the right atrium or beyond. The absence of metastases in many patients with vena caval extension is an intriguing aspect of this cancer's behavior (Gettman and Blute, 2002; Wotkowicz et al, 2008). Forty-five to 70 percent of patients with RCC and IVC thrombus can be cured with an aggressive surgical approach including RN and IVC thrombectomy (see **Key Points** box).

Overall, involvement of the venous system with RCC occurs in 4% to 10% of patients. IVC tumor thrombus should be suspected in patients with a renal tumor who also have lower extremity edema, isolated right-sided varicocele or one that does not collapse with recumbency, dilated superficial abdominal veins, proteinuria, pulmonary embolism, right atrial mass, or nonfunction of the involved kidney. Staging of the level of IVC thrombus is as follows: I, adjacent to the ostium of the renal vein; II, extending up to the lower aspect of the liver; III, involving the intrahepatic portion of the IVC but below the diaphragm; and IV, extending above the diaphragm. The prognostic significance of IVC thrombus level has been controversial. Most studies suggest that the incidence of locoregional or systemic progression

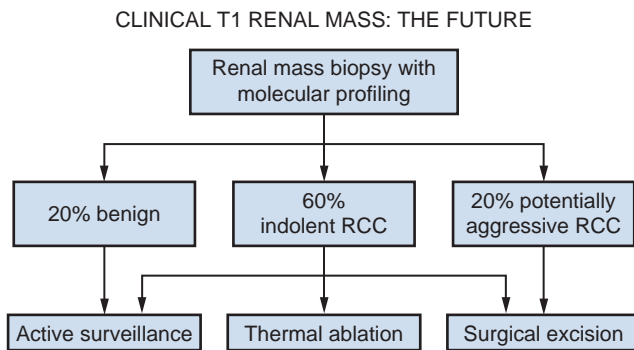

Figure 57-21. The American Urological Association guideline panel for the management of the clinical T1 renal mass strongly advocates research priority for renal mass biopsy with molecular profiling to facilitate more rational management of this patient population. RCC, renal cell carcinoma.

Figure 57-22. A, Computed tomography scan after administration of contrast agent shows bilateral solid and cystic renal masses in patient with von Hippel-Lindau disease. B, Histopathologic section of one of the renal cysts shows lining of clear cells representing incipient carcinoma.

KEY POINTS: TREATMENT OF LOCALLY ADVANCED RENAL CELL CARCINOMA

- Forty-five to 70 percent of patients with venous tumor thrombus can be cured with nephrectomy and thrombectomy.
- Thrombus extending into the IVC below the main hepatic veins can be readily managed with isolation of the involved vasculature and removal of the tumor thrombus.
- Thrombus extending above the main hepatic veins requires more extensive dissection, venovenous bypass, or cardiopulmonary bypass and circulatory arrest.
- For large tumors with radiographic suspicion of invasion into adjacent structures (cT4), complete excision with en bloc resection of the involved structures provides the only chance of cure.
- Bulky lymphadenopathy carries a poor prognosis similar to metastatic disease, although surgical resection should be considered if feasible and if appropriate given careful assessment of disease burden and patient age/comorbidities.
- High-quality preoperative imaging (CT or MRI) should be obtained in proximity to the anticipated surgery to plan for and achieve intraoperative success.
- Although locally advanced RCC is still primarily a surgical disease, adjuvant systemic therapy trials should be encouraged and, in select patients, neoadjuvant approaches may be considered.

Figure 57-23. Computed tomography scan demonstrating lower pole right renal cell carcinoma (*short arrows*) with level III inferior vena cava (IVC) thrombus. The *long arrow* indicates the upper extent of the tumor thrombus within the intrahepatic portion of the IVC. The *arrowhead* indicates extensive retroperitoneal venous collateral vessels associated with restricted flow within the IVC.

is higher in patients with level III-IV IVC thrombus, and this probably accounts for the reduced survival reported in this subgroup in some series (Sosa et al, 1984; Quek et al, 2001; Zisman et al, 2003; Kim et al, 2004; Leibovich et al, 2005a). Other series have shown that any IVC involvement is worse than renal vein involvement without distinction with regard to IVC level; in these series, other factors, such as nodal or metastatic involvement and tumor grade, have more impact on overall survival (Blute et al, 2004b; Terakawa et al, 2007). However, even patients with level IV IVC thrombi can be cured with surgical resection, in the absence of metastases and other adverse features (Libertino et al, 1987; Glazer and Novick, 1996; Ciancio et al, 2007; Granberg et al, 2008). The seventh edition of the TNM staging system distinguishes tumors with thrombi above the diaphragm (stage T3c) from those with IVC thrombi below the diaphragm (stage T3b) and those with thrombi only within the renal vein or its major branches (stage T3a) (Edge et al, 2010).

MRI is a noninvasive and accurate modality for demonstrating both the presence and the cephalad extent of vena caval involvement and has been the preferred diagnostic study at many centers for the past few decades (Goldfarb et al, 1990; Pouliot et al, 2010). Administration of gadolinium during the study often allows tumor thrombus to be differentiated from bland thrombus, because the latter does not demonstrate enhancement. More recent evidence suggests that multiplanar CT can provide essentially equivalent information (Fig. 57-23) (Ng et al, 2008; Guzzo et al, 2009). The importance of high-quality preoperative imaging cannot be overemphasized, and this imaging should be obtained as close as possible to the date of surgery because progression of the tumor thrombus may mandate important changes in intraoperative management (Blute et al, 2004b; Wotkowicz et al, 2008).

Invasive contrast-enhanced imaging is reserved for patients in whom MRI and CT findings are equivocal or for whom MRI and CT are contraindicated. Although inferior venacavography remains an accurate diagnostic study, this invasive technique is generally unnecessary in the modern imaging era. Renal arteriography can also be used as an adjunctive preoperative study; vascularization of IVC tumor thrombus is observed in 35% to 40% of cases (Fig. 57-24) (Novick et al, 1990; Wotkowicz et al, 2008). When this finding is present, preoperative embolization of the renal artery can

Figure 57-24. Right renal arteriogram shows arterialization of a supradiaphragmatic vena caval thrombus.

be considered in an attempt to shrink the thrombus and facilitate the surgical procedure. In patients with extensive supradiaphragmatic vena caval thrombi, when adjunctive cardiopulmonary bypass with deep hypothermic circulatory arrest is considered, coronary angiography should also be performed preoperatively (Novick et al,

1990). If significant obstructing coronary lesions are found, these can be repaired simultaneously during cardiopulmonary bypass.

Transesophageal echocardiography is an invasive study that is unnecessary before surgery, but can be an important intraoperative diagnostic modality for evaluation of thrombus extension, monitoring for embolic phenomena, recognition of residual tumor during and after resection, and assessment of preload/cardiac function during IVC clamping (Glazer and Novick, 1997; Wotkowicz et al, 2008; Cywinski and O'Hara, 2009; Shuch et al, 2009).

The surgical approach is tailored to the level of IVC thrombus, but uniformly begins with careful mobilization of the kidney and early ligation of the arterial blood supply (Blute et al, 2004b; Shuch et al, 2009; Gorin et al, 2012b). In general, level I thrombi are isolated by a Satinsky clamp and are thus readily addressed (Fig. 57-25A). Level II thrombi require sequential clamping of the caudal IVC, contralateral renal vasculature, and cephalad IVC along with mobilization of the relevant segment of the IVC and occlusion of lumbar veins. The renal ostium is then opened and the thrombus is removed, all in a bloodless field (Fig. 57-25B). When tumor thrombus invades the wall of the vena cava, aggressive resection of the involved cava and attainment of negative surgical margins are required to minimize the risk of recurrence (Blute et al, 2007; Wotkowicz et al, 2008). IVC grafting or reconstitution is required in

some instances, but patients with a completely occluded IVC do not require this because of collateral blood flow (Sarkar et al, 1998; Blute et al, 2007; Hyams et al, 2011). Distal bland thrombus within the IVC or iliac vessels may be left in situ, although the IVC should be ligated or clipped cephalad to this level to prevent pulmonary embolism.

Vascular control for level III and level IV IVC thrombi requires more extensive dissection, venovenous bypass, or cardiopulmonary bypass and hypothermic circulatory arrest. For level III thrombi, mobilization of the liver and exposure of the intrahepatic IVC will often allow the thrombus to be mobilized caudad to the hepatic veins, and venous isolation can then proceed as for a level II thrombus (Fig. 57-25C) (Gallucci et al, 2004). If this is not possible, the IVC should be clamped above the liver and a Pringle maneuver performed to temporarily occlude the portal triad (Ciancio et al, 2007, 2011). Venovenous bypass is commonly used in these cases but may not be required if adequate collateral flow is present. Level IV IVC thrombi have traditionally been managed with cardiopulmonary bypass and hypothermic circulatory arrest, and this is still the preferred approach in complex cases (Blute et al, 2007; Wotkowicz et al, 2008). However, many centers are now trying to avoid hypothermic circulatory arrest because of the hypo-coagulable state that ensues when coming off the pump and

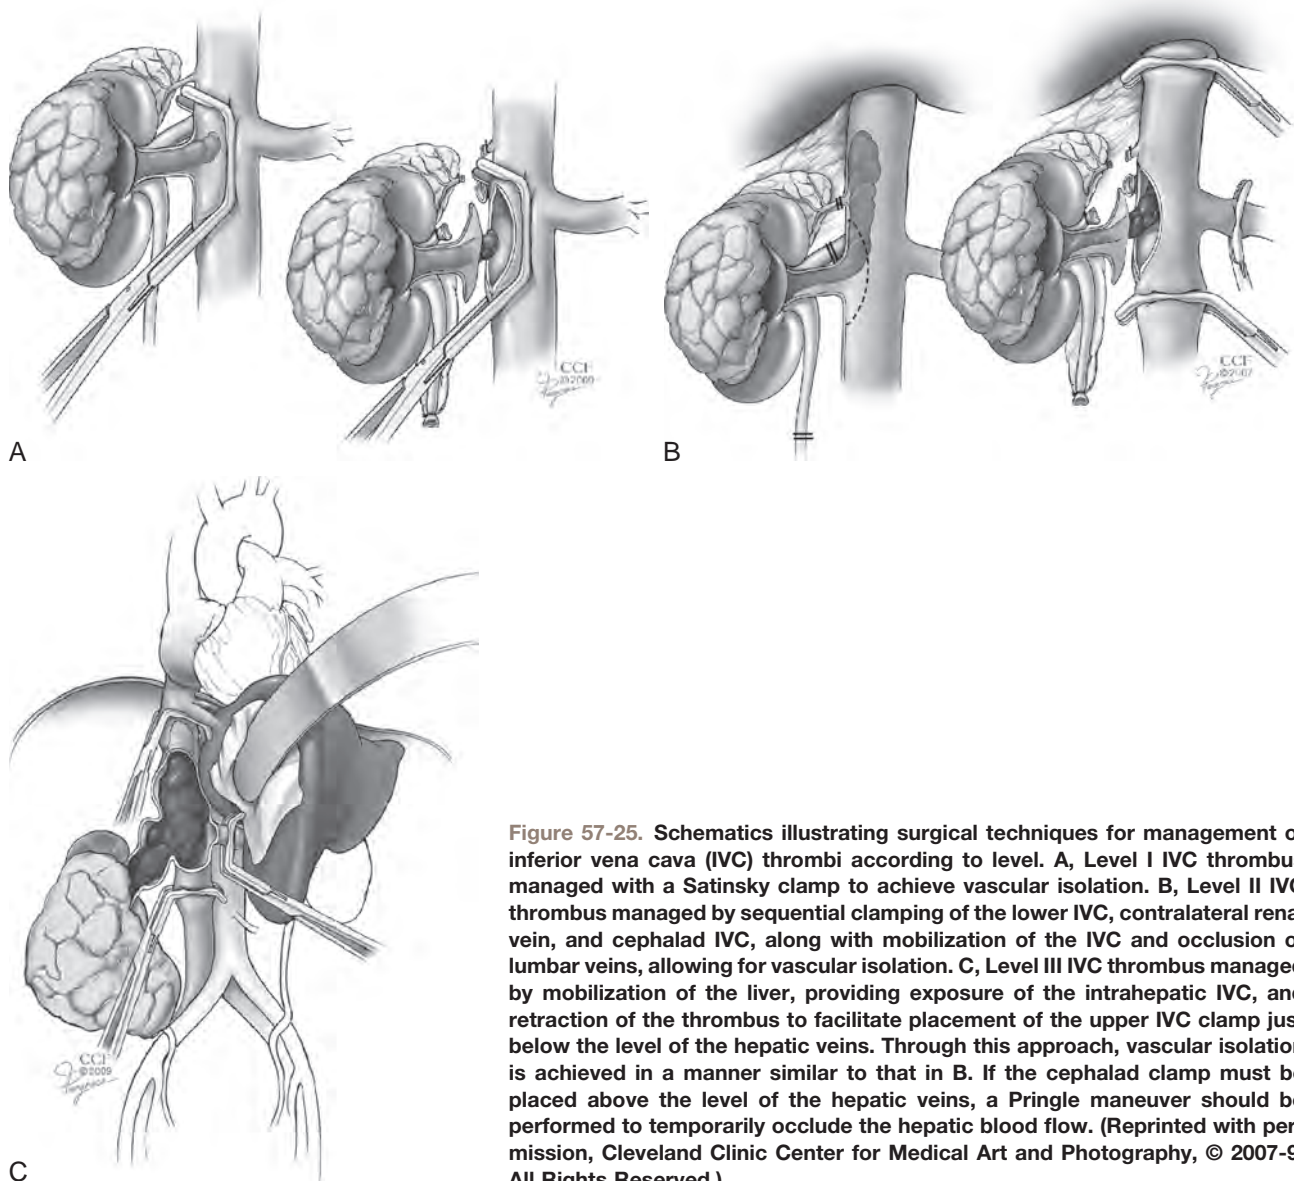

Figure 57-25. Schematics illustrating surgical techniques for management of inferior vena cava (IVC) thrombi according to level. A, Level I IVC thrombus managed with a Satinsky clamp to achieve vascular isolation. B, Level II IVC thrombus managed by sequential clamping of the lower IVC, contralateral renal vein, and cephalad IVC, along with mobilization of the IVC and occlusion of lumbar veins, allowing for vascular isolation. C, Level III IVC thrombus managed by mobilization of the liver, providing exposure of the intrahepatic IVC, and retraction of the thrombus to facilitate placement of the upper IVC clamp just below the level of the hepatic veins. Through this approach, vascular isolation is achieved in a manner similar to that in B. If the cephalad clamp must be placed above the level of the hepatic veins, a Pringle maneuver should be performed to temporarily occlude the hepatic blood flow. increased risk of cerebrovascular accident and myocardial infarction (Ciancio et al, 2011; Navia et al, 2012). If the thrombus is mobilized below the atrium, sequential vascular control can often be achieved without opening the heart (Ciancio et al, 2010). Further detail about these procedures can be found in Chapter 60.

The risk of morbidity can be substantial for thrombi extending above the diaphragm, and mortality rates associated with RN and IVC thrombectomy have been reported to be as high as 5% to 10% in some series, depending on patient comorbidities and tumor characteristics (Blute et al, 2004b; Ciancio et al, 2010; Navia et al, 2012). Therefore patient selection and surgical planning are of paramount importance (Ciancio et al, 2010; Pouliot et al, 2010). Although there may be a palliative role for surgery in some patients with metastasis who experience severe disability from intractable edema, ascites, cardiac dysfunction, or associated local symptoms such as abdominal pain and hematuria, most such patients will not benefit due to risk of perioperative morbidity and limited life expectancy (Slaton et al, 1997; Culp et al, 2010).

Locally Invasive Renal Cell Carcinoma

The sequestered location of RCC results in occasional patients presenting with large primary tumors that invade adjacent structures. Patients with pathologic stage T4 disease have represented less than 2% of surgical series, but this proportion will increase with the reclassification of adrenal involvement into this category (Thompson et al, 2005a; Karellas et al, 2009). Patients with locally advanced RCC usually present with pain, generally from invasion of the posterior abdominal wall, nerve roots, or paraspinal muscles. Large tumors may indent and compress adjacent liver parenchyma but seldom actually grow by direct extension into the liver, and intrahepatic metastases are more common (Yezhelyev et al, 2009). Margulis and colleagues (2007a) reported that invasion of adjacent organs was confirmed pathologically in only 40% of the patients in whom it was suspected on preoperative imaging. Duodenal and pancreatic invasion is uncommon and a poor prognostic sign. The propensity for RCC to parasitize vessels may account for extension into the colon and its mesentery. In evaluation of patients with large, invasive upper quadrant abdominal masses, a broad differential diagnosis should be considered, including adrenocortical carcinoma, urothelial carcinoma, sarcoma, and lymphoma, in addition to locally invasive RCC.

Because surgical therapy is the only potentially curative management for RCC, extended operations with en bloc resection of adjacent organs are occasionally indicated. Complete excision of the tumor, including resection of the involved bowel, spleen, or abdominal wall muscles, is the aim of therapy. However, even with an aggressive surgical approach the prognosis remains poor. In the series from Margulis and colleagues (2007a), 10 of 12 patients with pathologic T4 disease experienced disease recurrence at a median of 2 months after surgery. Similarly, although negative surgical margins were achieved in 63% of patients in another series,

34 of 38 patients (90%) ultimately died of disease at a median of 12 months after surgery (Karellas et al, 2009). For these reasons, neoadjuvant systemic therapy is a valid consideration for patients with potentially “unresectable” RCC because it can provide a “litmus test” to identify patients who are destined to progress rapidly.

Important perioperative concerns for patients with locally advanced RCC include a comprehensive preoperative consent, including the potential for increased morbidity and resection of adjacent organs, a full bowel preparation, and consideration for preoperative embolization of the renal arterial blood supply. The latter may reduce bleeding if there is a contentious renal hilum as a result of encasement of the vessels or bulky lymphadenopathy. Vaccination against *Streptococcus pneumoniae*, *Haemophilus influenzae* type B, and *Neisseria meningitidis* should be performed preoperatively when splenectomy is likely during nephrectomy (Shatz, 2005; Habermalz et al, 2008). If not already immunized, splenectomized patients should receive these vaccines in the postsurgical setting to prevent sepsis caused by one of these encapsulated organisms (Shatz, 2005; Habermalz et al, 2008).

Incomplete excision of a large primary tumor, or debulking, is rarely indicated as survival estimates are only 10% to 20% at 12 months (Dekernion et al, 1978; Karellas et al, 2009). The role of radiation therapy in the treatment of locally extensive RCC is controversial. Several early studies suggested that preoperative radiotherapy could improve survival (Cox et al, 1970). A subsequent study by van der Werf-Messing (1973), however, compared results for preoperative therapy with controls and found no survival difference at 5 years. Routine postoperative radiotherapy has not been shown to influence overall survival and can be hazardous because of proximity of small bowel, which is highly radiosensitive.

Lymph Node Dissection for Renal Cell Carcinoma

The need for extensive lymphadenectomy in patients undergoing RN remains controversial, as a randomized trial of lymphadenectomy at nephrectomy failed to show a distinct advantage (Leibovich and Blute, 2008; Blom et al, 2009; Crispen et al, 2011). The main limitation of this trial was the inclusion of patients at low risk for nodal metastasis (81% were grade 1 or 2 and 72% were organ confined); lymph node metastases were present in only 4% of patients undergoing complete lymph node dissection (Blom et al, 2009). Based on this trial, a compelling argument for lymph node dissection in patients with clinically localized RCC cannot be supported. Of greater impact is the study from Blute and colleagues (2004a) who elucidated pathologic features associated with increased risk for nodal metastases, as detailed in Table 57-19. Based on this study and a subsequent prospective evaluation of this approach, patients with two or more of these risk factors should be considered for extensive lymph node dissection incorporating ipsilateral great vessel and interaortocaval regions and extending from

TABLE 57-19 Risk of Regional Lymph Node Metastases in Renal Cell Carcinoma Based on Pathologic Risk Factors

NO. OF RISK FACTORS*	PERCENTAGE OF PATIENTS IN THIS RISK GROUP	PERCENTAGE WITH POSITIVE LYMPH NODES IN RETROSPECTIVE SERIES†	PERCENTAGE WITH POSITIVE LYMPH NODES IN PROSPECTIVE SERIES‡
0	44% (729/1652)	0.4% (3/729)	—
1	18% (302/1652)	1.0% (3/302)	—
2	17% (276/1652)	4.4% (12/276)	20% (7/35)
3	13% (209/1652)	12% (26/209)	37% (26/71)
4	7.3% (121/1652)	13% (16/121)	49% (26/53)
5	0.9% (15/1652)	53% (8/15)	50% (5/10)

*Risk factors include grade 3 or 4, sarcomatoid component, tumor size ≥ 10 cm, pathologic stage T3 or pT4, and histologic tumor necrosis.

†Data from Blute et al, 2004a; lymph node dissection performed in 58% of 1652 patients overall.

‡Data from Crispen et al, 2011; lymph node dissection performed in 41% of 415 patients with 2+ risk factors.

the crus of the diaphragm to the common iliac artery. Forty-five percent of these patients had positive lymph nodes outside of the renal hilar region (Fig. 57-26) (Crispin et al, 2011).

Local Recurrence after Radical Nephrectomy or Nephron-Sparing Surgery

Local recurrence of RCC after RN, which includes recurrence in the renal fossa, ipsilateral adrenal gland, or ipsilateral retroperitoneal lymph nodes, is an uncommon event, occurring in 2% to 4% of cases (Margulis et al, 2009). Risk factors include locally advanced or node-positive disease and adverse histopathologic features (Esrig et al, 1992; Sandock et al, 1995; Levy et al, 1998). In contrast, local recurrence after RN is rare in patients with organ-confined RCC. Only about 40% of local recurrences are isolated; the majority of patients with local recurrence also have systemic disease, and a thorough metastatic evaluation should be pursued (Schrodter et al, 2002; Eggener et al, 2008).

Surgical resection of isolated local recurrence of RCC after RN should be considered, because it can provide long-term cancer-free status for 30% to 40% of patients (Master et al, 2005; Bandi et al, 2008; Margulis et al, 2009). Complete resection of abdominal recurrences is often a formidable task because the natural tissue barriers are no longer present and invasion of contiguous organs is common. En bloc resection of adjacent organs is often required, and the risk of morbidity can be substantial (Gogus et al, 2003; Eggener et al, 2008; Margulis et al, 2009). Margulis and colleagues (2009) have reported on 54 patients with local recurrence after nephrectomy managed by surgical resection, 69% of whom also received adjunctive systemic therapy. Risk factors associated with cancer-specific death after resection included recurrent tumor size, sarcomatoid features in the recurrence specimen, positive surgical margins, abnormal alkaline phosphatase, and increased lactate dehydrogenase. Patients with 0, 1, and greater than 1 adverse risk features demonstrated cancer-specific survival times of 111, 40, and 8 months, respectively. Intraoperative radiation has not been found to be of oncologic benefit (Master et al, 2005), but radiation therapy may be of value for palliation of symptomatic local recurrence in patients who are not operative candidates.

Local recurrence in the remnant kidney after PN for RCC has been reported in 1.4% to 10% of patients, and the main risk factor is advanced T stage (Campbell and Novick, 1994; Lane and

Gill, 2007; Krambeck et al, 2008). Most of these local recurrences are distant from the tumor bed and are thus probably a result of unrecognized tumor multicentricity or de novo occurrence rather than true treatment failure (Campbell and Novick, 1994; Lane and Novick, 2007; Krambeck et al, 2008). Recent data confirm that local recurrence after PN is uncommon, even with a positive surgical margin (Permpongkosol et al, 2006b; Kwon et al, 2007; Kutikov et al, 2008; Yossepowitch et al, 2008). Patients with isolated local recurrence after PN can be considered for repeat PN, completion nephrectomy, TA, or AS (Bratslavsky et al, 2008; Johnson et al, 2008; Magera et al, 2008a; Berger et al, 2009b). TA is now being used more frequently in this setting because of concern about fibrosis within the renal fossa, but conventional PN can and should be performed when anatomy and tumor characteristics are amenable (Gittes and Blute, 1982; Moll et al, 1993; Campbell and Novick, 1994; Frank et al, 2005; Bratslavsky and Linehan, 2011). Regardless, tumor characteristics, age and comorbidities, disease-free interval, and renal function status should all be considered during patient counseling, and a biopsy of the recurrent tumor may also be useful.

Local recurrence after TA often represents treatment failure; many local recurrences develop within the previous tumor bed (McDougal et al, 2005; Matin et al, 2006; Levinson et al, 2008; Nguyen et al, 2008b; Berger et al, 2009b). Reported incidences range between 3% and 10% for cryoablation and between 5% and 20% for RFA (Kunkle and Uzzo, 2008; Kunkle et al, 2008; Levinson et al, 2008; Weight et al, 2008; Berger et al, 2009b). Importantly, the true incidence of local recurrence in this population is not well defined because radiographic factors predictive of recurrence have been challenged, particularly for RFA; most studies have not incorporated routine biopsy of the tumor bed during surveillance, and length of follow-up in many series is limited (Stein and Kaouk, 2007; Weight et al, 2007). Most of these recurrences can be managed with repeat ablation, but this is not always feasible. Beyond this, management options are similar to those for recurrence after PN, with the caveat that salvage surgery in this setting is often challenging owing to the dense inflammatory reaction induced by TA (Nguyen et al, 2008b; Kowalczyk et al, 2009).

Adjuvant Therapy for Renal Cell Carcinoma

Unfortunately, recurrence develops in a significant proportion of patients thought to be rendered disease free after surgical resection, primarily due to occult micrometastatic disease. Although postsurgical recurrence is not common in patients with low-stage, organ-confined disease, locally advanced RCC and RCC with other adverse histopathologic features carry a significant risk of recurrence. Various predictive tools can assist in the assessment of the risk in individual patients (Kim et al, 2012a), although on the whole, distant metastases develop in 20% to 35% and local recurrence in 2% to 5% of patients (Lane and Kattan, 2008). In view of these findings, a strong rationale for systemic adjuvant therapy exists in high-risk patients. However, none of the adjuvant studies in this field have been convincingly positive thus far, and the standard of care remains observation if the patient will not consider an adjuvant trial (see Key Points box).

The primary clinical end point used in most adjuvant trials has been recurrence-free survival. Ideal trial design incorporates placebo-controlled and blinded protocols and independent radiographic review to confirm that all entered patients are truly disease free at study entry and to confirm and accurately time all recurrences. Intent-to-treat analysis is another strong expectation in this field (Kenney and Wood, 2012). Until recently, many adjuvant trials for patients with RCC have been underpowered to detect small differences in survival, and primary end points related to tumor recurrence have been difficult to assess in view of flaws in study design. A variety of adjuvant approaches have been investigated, including hormonal manipulation, radiotherapy, immunotherapeutics, vaccines, and, most recently, targeted molecular agents. Early adjuvant trials tested postoperative medroxyprogesterone acetate (Pizzocaro et al, 1987) or perioperative radiotherapy (van der Werf-Messing, 1973) with negative results.

KEY POINTS: TREATMENT OF LOCAL RECURRENCE AND ADJUVANT THERAPY FOR RENAL CELL CARCINOMA

- Isolated local recurrence after RN occurs in 2% to 4% of patients, and a thorough metastatic evaluation should be pursued if resection is under consideration.
- Local recurrence after PN is more common at sites distant from the tumor bed and can be managed by repeat PN, completion nephrectomy, TA, or AS.
- Local recurrence after TA often reflects incomplete tumor eradication; management options include repeat ablation, AS, or salvage surgery.
- Despite a significant likelihood of recurrence of RCC with poor-risk features, there is no established evidence of a benefit for adjuvant therapy in patients who appear to be cancer free after surgical resection, and observation remains the standard of care.
- Ongoing adjuvant clinical trials investigating targeted molecular agents and other novel systemic approaches should be supported in an effort to identify an efficacious adjuvant strategy.

Despite demonstrable antitumor effects in patients with metastatic disease, IL-2 and interferon alfa did not prove to be beneficial in the adjuvant setting. Four randomized studies were performed, three with interferon alfa and one with IL-2 (Pizzocaro et al, 2001; Clark et al, 2003; Messing et al, 2003). The studies investigating interferon used various doses, preparations (L-interferon, interferon alfa-2a, interferon alfa-2b), and duration of therapy; none demonstrated a benefit when compared with controls. Clark and colleagues (2003) randomized 69 high-risk patients after complete surgical resection to observation versus high-dose IL-2. An interim analysis prompted closure of the trial primarily because of the toxicity of high-dose IL-2; there was no clinically meaningful benefit for the population as a whole or in the subgroups that were analyzed.

A variety of autologous tumor vaccine–based approaches have been used to immunize RCC patients in the postoperative setting, again with essentially negative results (Galligioni et al, 1996;

Jocham et al, 2004; Wood et al, 2008). More recently, the results of the ARISER adjuvant trial were released, representing another negative adjuvant trial for RCC. This study investigated girentuximab, a chimeric monoclonal antibody directed against G250, a cell surface antigen expressed by the majority of clear cell RCC. In 2012, the interim analysis showed no improvement in median disease-free survival, and the trial was terminated.

Current trials using targeted molecular agents with activity in patients with metastatic RCC have enrolled a large number of patients with surgically resected RCC who are at high risk for recurrence (Table 57-20) (Jonasch and Tannir, 2008; Kenney and Wood, 2012). These agents are orally administered and thus their use is appealing in an adjuvant setting, although there are many uncertainties regarding optimal choice of agent and dose and duration of therapy. In addition, the toxicities of these agents may limit their usefulness in the adjuvant setting because patients taking a potentially preventive treatment tend to have a much lower threshold for toxicities. Some of these trials have completed accrual and final analysis can be expected in approximately 2015. Please refer to Chapter 63 for a more detailed discussion of these targeted treatments and their rationale for patients with advanced RCC.

OTHER MALIGNANT RENAL TUMORS**Sarcomas of the Kidney**

Sarcomas represent 1% to 2% of all malignant renal tumors in adults, with a peak incidence in the fifth decade of life (Vogelzang et al, 1993; Miller et al, 2010b). Renal sarcoma is less common but more lethal than sarcoma of any other genitourinary site, including the prostate, bladder, and paratesticular region (Russo et al, 1992). Differentiation of renal sarcoma from sarcomatoid RCC is often difficult on the basis of clinical presentation, radiographic findings, and, in some cases, pathologic analysis. Identification of any features of the various subtypes of RCC excludes the diagnosis of primary renal sarcoma. The common signs and symptoms associated with renal sarcoma in adults include palpable mass, abdominal or flank pain, and hematuria and are similar to those seen with large, rapidly growing RCCs (Economou et al, 1987). Specific findings suggestive of sarcoma rather than RCC

TABLE 57-20 Ongoing Clinical Trials of Adjuvant Treatment for Renal Cell Carcinoma (RCC)

TRIAL	STUDY GROUPS	TREATMENT DURATION	INCLUSION CRITERIA
Adjuvant Sorafenib or Sunitinib for Unfavorable Renal Cell Carcinoma (ASSURE)	Sunitinib vs. sorafenib vs. placebo	1 year	Clear cell and non-clear cell RCC eligible Stage T2-T4 or stage T1b and G3-4 N1 if complete dissection performed
Sorafenib for Patients with Resected Primary Renal Cell Carcinoma (SORCE)	Sorafenib (for 1 or 3 years) vs. placebo	3 years	Clear cell and non-clear cell RCC eligible Mayo Clinic progression score 3-11
Sunitinib vs. Placebo for the Treatment of Patients at high risk for Recurrent Renal Cell Cancer (S-TRAC)	Sunitinib vs. placebo	1 year	Predominant clear cell histology eligible High-risk RCC according to UISS*
Everolimus for Renal Cancer Ensuing Surgical Therapy (EVEREST)	Everolimus vs. placebo	1 year	Clear cell and non-clear cell RCC eligible Stage T2-T4 or stage T1b and G3-4 N1 if complete dissection performed
Adjuvant Axitinib Treatment of Renal Cancer (ATLAS)	Axitinib vs. placebo	3 years	Clear cell predominant (>50%) eligible pT2 and G3-4, or pT3a and > 4 cm, or pT3b/pT3c/pT4, or N1
Pazopanib as an Adjuvant Treatment for Locally Advanced Renal Cell Carcinoma (PROTECT)	Pazopanib vs. placebo	1 year	Clear cell predominant (>50%) eligible pT2 and G3-4, pT3, pT4, or N1

*UISS: UCLA Integrated Staging System (Zisman et al, 2002).

include apparent origin from the capsule or perisinuous region, growth to large size in the absence of lymphadenopathy, presence of fat or bone suggestive of liposarcoma or osteosarcoma, and hypovascular pattern on angiography, although one notable exception is the hemangiopericytoma, which is highly vascular (Shirkhoda and Lewis, 1987). Renal sarcoma should be suspected in any of these circumstances or in any patient with a very large or rapidly growing renal mass (Table 57-21).

Sarcomas of the kidney, like sarcomas of any other site, share in common a distinct tumor biology that has important implications with respect to management (Russo et al, 1992). These tumors are derived from mesenchymal components and are thus free of many of the natural barriers to dissemination that confine other tumor types. They are typically surrounded by a pseudocapsule that is often infiltrated with cancer cells, which can extend for some distance into the surrounding tissues. In many cases this cannot be recognized macroscopically, although it is often manifested in the form of local recurrences, which are common after surgical extirpation, even when a wide excision has been performed. High-grade sarcomas often metastasize, with the lungs being a primary site of spread, and prognosis is poor; many patients die of disease progression in a matter of months. Low-grade sarcomas tend to pursue a more indolent course, although local recurrences often require repeat resection to prolong survival and minimize morbidity.

In general, the most important prognostic factors for sarcomas are margin status and tumor grade. The initial resection is the key event because this is the best chance for a long-term cure. For renal sarcomas this often mandates RN along with en bloc excision of adjacent organs (Brescia et al, 2008; Wang et al, 2011). MRI can be useful for preoperative planning by defining tissue planes and proximity to vital structures. This is primarily a surgical disease, and wide excision is the goal with intraoperative monitoring of margin status. Chemotherapeutic agents that have demonstrated activity against metastatic sarcomas include doxycycline and ifosfamide, but even in the best of circumstances response rates are disappointing (Antman et al, 1993; Miller et al, 2010b). The

combination of radiation therapy and chemotherapy, which has proved effective in an adjuvant setting for the management of sarcomas of the extremity, has not provided much benefit for renal or retroperitoneal sarcomas (Russo et al, 1992). At present, the role of such adjuvant approaches for the management of renal sarcomas is not well defined, although a multimodal approach is often pursued if performance status allows, given the poor prognosis.

The largest single-institution series of renal sarcomas include only 15 to 41 cases and represent a composite experience extending for a period of several years (Shirkhoda and Lewis, 1987; Wang et al, 2011). In all such series leiomyosarcoma has been the most common histologic subtype, and in many series liposarcoma has been the second most common. In contrast, for retroperitoneal sarcomas, the order is reversed, with liposarcoma being the most common histologic subtype (Karakousis et al, 1995). All such series report a poor prognosis; the experience of Srinivas and colleagues (1984) at Memorial Sloan Kettering Cancer Center is representative. In this series of 16 patients with renal sarcomas, 15 underwent nephrectomy, often with en bloc excision of adjacent organs; 5 received adjuvant radiation therapy and chemotherapy without apparent benefit; and 13 died within 6 months after surgery. Saitoh and colleagues (1982) defined the common sites of metastases of renal sarcomas: lung first and foremost but also lymph nodes and liver.

Leiomyosarcoma is the most common histologic subtype of renal sarcoma, accounting for 50% to 60% of such tumors (Fig. 57-27). The cell of origin is the smooth muscle cell of the capsule or other perinephric structures (Moudouni et al, 2001; Deyrup et al, 2004; Wang et al, 2011). Niceta and associates (1974) identified 66 cases of renal leiomyosarcoma in the literature and reported a female predominance; most patients presented in the fourth through sixth decades of life. Renal leiomyosarcoma, like other renal sarcomas, tends to displace rather than invade the parenchyma, and is characterized by rapid growth rate, frequent metastasis, and high local and systemic recurrence rates (Deyrup et al, 2004). In the cases reviewed by Niceta and associates (1974), most patients were treated primarily with RN and died within 2 years. In the Mayo Clinic series, 14 of 15 patients with renal leiomyosarcoma

TABLE 57-21 Characteristics of Other Malignant Renal Tumors

TUMOR TYPE	CHARACTERISTICS	MANAGEMENT
Sarcomas	Leiomyosarcoma most common Typically hypovascular Often rapidly growing and occasionally appear to be derived from the renal capsule	Wide local excision with confirmation of negative margins
Renal lymphoma and leukemia	Multiple radiographic patterns described Typically hypovascular Suspect in patients with massive retroperitoneal lymphadenopathy or lymphadenopathy in other regions of the body or atypical locations	Biopsy should be considered Extirpative surgery should be avoided Typically managed with chemotherapy and/or radiation therapy
Metastatic tumors	Most common sources include lung, breast, and gastrointestinal cancers, malignant melanoma, and hematologic malignancies Typically hypovascular and multifocal	Biopsy should be strongly considered Typically managed with systemic therapy or palliative care
Carcinoid	Typically hypovascular May present as carcinoid syndrome Derived from neuroendocrine cells	Surgical excision
Small cell carcinoma of the kidney	Neuroendocrine derivation Typically hypovascular Most locally advanced or metastatic	Multimodal therapy with surgery and platinum-based chemotherapy
Primitive neuroectodermal tumor	Derived from primitive neural crest cells Hypovascular pattern typical Poor prognosis	Multimodal therapy
Wilms tumor	Heterogeneous solid renal mass on computed tomography	Multimodal therapy analogous to treatment protocols for pediatric Wilms tumor

Figure 57-27. A, Computed tomography scan demonstrates a large leiomyosarcoma of the left kidney. B, Microscopic features of leiomyosarcoma include spindle cells, blunt-ended nuclei, and eosinophilic cytoplasm. (Courtesy Dr. Michael McGuire, Evanston, IL and Dr. Ming Zhou, Cleveland, OH.)

died of disease progression within 4 months to 5.5 years after surgery (Frank et al, 2000).

Other than leiomyosarcoma, a wide variety of histologic subtypes have been described because almost every conceivable type of sarcoma has been found in the kidney. **Liposarcoma** is readily distinguished from RCC because of the presence of adipose tissue, but is often confused with AMLs or large, benign renal lipomas (Frank et al, 2000). Renal liposarcoma typically develops in the fifth and sixth decades of life and often grows to extremely large size. Response to radiation therapy and cisplatin-based chemotherapy in an adjuvant setting has been reported by Beldegrun and deKernion (1987) and should be considered in patients with high-grade disease or positive margins. **Osteogenic sarcoma** is a rare but distinctive form of renal sarcoma that contains calcium and is often rock hard (Micolonghi et al, 1984; Leventis et al, 1997). Extensive calcification in a large, hypovascular tumor should suggest the diagnosis. The appearance on plain films can mimic a staghorn calculus, but the readily evident mass effect should suggest xanthogranulomatous disease or, more rarely, osteogenic sarcoma. Again, prognosis is poor; most patients die of disease progression within a few years after diagnosis. **Less common histologic subtypes include** rhabdomyosarcoma, fibrosarcoma, carcinosarcoma, malignant fibrous histiocytoma, synovial sarcoma, schwannoma, angiosarcoma, and malignant hemangiopericytoma (Srigley et al, 2013). Malignant hemangiopericytomas are notable for their extensive vascularity (Chaudhary et al, 2007; Brescia et al, 2008). Preoperative angioembolization has been described and may simplify surgical excision (Smullens et al, 1982).

Renal Lymphoma and Leukemia

Renal involvement with hematologic malignancies, which include the lymphomas and leukemias, is common—it is found at autopsy in approximately 34% of patients dying of progressive lymphoma or leukemia. However, these processes are uncommonly seen in clinical practice because they are often silent and generally occur only as a late manifestation of systemic disease (Pollack et al, 1987; McVary, 1991). The role of the urologist in the evaluation of renal lymphoma or leukemia is critically important and can include differentiation from other renal malignant neoplasms, timely provision of a pathologic diagnosis, and preservation of renal function (McVary, 1991). Renal involvement is more common with non-Hodgkin lymphoma than with Hodgkin disease, and, as with most other forms of extranodal non-Hodgkin

TABLE 57-22 Computed Tomographic Findings Associated with Lymphoma

FINDING	INCIDENCE (%)
Multiple renal masses	45
Solitary renal mass	15
Renal invasion from enlarged retroperitoneal lymph nodes	25
Diffuse renal involvement	10
Predominantly perinephric involvement	5

Data from Pollack et al, 1987, and Heiken et al, 1991.

lymphoma, histologically diffuse forms predominate over nodular forms (Pollack et al, 1987; O’Riordan et al, 2001). Primary renal lymphoma is rare, with only a few well-documented case reports in the literature (Pollack et al, 1987; Ahmad et al, 2005; Garcia et al, 2007). This is not surprising given the relative paucity of lymphoid tissue in the normal renal parenchyma. Hematogenous dissemination of lymphoma to the kidney is most common and is thought to occur in 90% of cases; direct extension from retroperitoneal lymph nodes accounts for the remainder. Hartman and colleagues (1982) have shown that the most common pattern of renal involvement consists of multiple small renal nodules that tend to develop between the individual nephrons. Eventually, these nodules become confluent, forming radiographically detectable masses. At the extreme, they can replace the entire parenchyma of the kidney, leading to renal failure.

The CT scan is the radiographic modality of choice for the diagnosis of renal lymphoma and for monitoring response to therapy (Pollack et al, 1987; Urban and Fishman, 2000). The common radiographic patterns associated with renal lymphoma have been defined by Heiken and associates (1991) and confirmed by a number of other investigators (Table 57-22). Renal lymphoma can present as multiple distinct renal masses; as a solitary renal mass, which can be difficult to differentiate from RCC; as diffuse renal infiltration; or as direct invasion of the kidney from enlarged retroperitoneal nodes (Sheth et al, 2006). A hypovascular pattern on angiography is typical for renal lymphoma (Pollack et al, 1987). Renal lymphoma should be suspected in patients with massive retroperitoneal lymphadenopathy, splenomegaly, or lymphadenopathy in other regions of the body or atypical regions within

the retroperitoneum. Relative to this, the main landing zones for RCC should be kept in mind—the interaortocaval region for right RCC and para-aortic region for left RCC—and lymphadenopathy centered outside of these areas should raise suspicion for lymphoma. Any patient with a prior history of lymphoma and a renal mass should also be evaluated for renal recurrence rather than for RCC. In general, lymphomas are more common in patients with iatrogenic immune suppression, acquired immunodeficiency syndrome, autoimmune diseases, or graft-versus-host disease and in patients with a history of radiation therapy (McVary, 1991). These clinical associations may also increase the index of suspicion about a diagnosis of systemic lymphoma.

Renal involvement related to leukemia is more common in children, paralleling the demographics of the disease, and is more commonly due to lymphocytic leukemia than the myelogenous forms (Pollack et al, 1987). Leukemia typically involves the kidney in a diffusely infiltrative pattern and most often represents a late manifestation of systemic disease.

If lymphoma or leukemic renal involvement is suspected, consideration should be given to percutaneous biopsy or aspiration to obtain a pathologic diagnosis (Herts, 2012); if exploratory surgery is necessary, intraoperative biopsy and frozen-section analysis should take priority. Extirpative surgery should be avoided if renal lymphoma and leukemia are suspected because the primary treatment of these processes is systemic chemotherapy with or without radiation therapy (McVary, 1991). The classic chemotherapy regimen for non-Hodgkin lymphoma is the CHOP protocol, which includes cyclophosphamide, doxorubicin, vincristine, and prednisolone (Colevas et al, 2000). Nephrectomy is seldom indicated except in patients with severe symptoms, such as uncontrollable hemorrhage. The other notable exception is the extremely rare patient with primary renal lymphoma in whom a combination of nephrectomy and systemic chemotherapy may represent optimal therapy (Garcia et al, 2007; Hart et al, 2012). Fourteen cases of marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue localized to the kidney have been described, with some apparently cured by surgery alone (Garcia et al, 2007).

Both renal lymphoma and leukemia are commonly silent but can be associated with hematuria, flank pain, or progressive renal failure. Fever, weight loss, and fatigue, the so-called B symptoms of lymphoma, are much more common (Zomas et al, 2004). Renal failure can be due to extensive replacement of the functioning parenchyma or bilateral ureteral obstruction associated with enlarged retroperitoneal lymph nodes (McVary, 1991). In reality, renal failure in such patients is more often related to medical causes, such as hypercalcemia or urate nephropathy, which can develop during systemic treatment of advanced disease.

Metastatic Tumors

Metastatic tumors are the most common malignant neoplasms in the kidney, outnumbering primary renal tumors by a wide margin. Autopsy studies have shown that 12% of patients dying of cancer have renal metastases, making the kidney one of the most common sites for metastatic dissemination (Pollack et al, 1987). The profuse vascularity of the kidney makes it a fertile soil for the deposition and growth of cancer cells. Almost all renal metastases develop through a hematogenous route of spread. Direct invasion of tumors derived from adjacent organs such as the pancreas, colon, and adrenal gland is much less common. The most frequent sources of renal metastases include lung, breast, and gastrointestinal cancers, malignant melanoma, and the hematologic malignant neoplasms (Choyke et al, 1987; Pollack et al, 1987; Aron et al, 2004; Stage et al, 2005). Of the solid malignant neoplasms, lung cancer is most commonly associated with renal metastases. Olsson and colleagues (1971) found that 20% of patients dying of lung cancer had renal metastases, 60% of which were bilateral. Klinger (1951) reviewed 5000 autopsies and found 17 cases of renal metastases from lung cancer, 11 from gastric cancer, 9 from breast cancer, 7 from pancreatic cancer, 4 from esophageal cancer, 6 from other gastrointestinal primary cancers, and 1 from

malignant melanoma. Most renal metastases are multifocal, and almost all are associated with widespread nonrenal metastases (Pollack et al, 1987; Choyke et al, 2003). Choyke and associates (1987) reported that renal metastases from lung, breast, and colon carcinomas are notable because they are occasionally large and solitary, making them difficult to differentiate from RCC.

The typical pattern of renal metastases consists of multiple small nodules that are often clinically silent, although they can lead to hematuria or flank pain in exceptional circumstances (Pollack et al, 1987). CT typically demonstrates isodense masses that enhance only moderately (5 to 30 HU) after administration of intravenous contrast material (Pollack et al, 1987).

Renal metastases should be suspected in any patient with multiple renal lesions and widespread systemic metastases or a history of nonrenal primary cancer. If there is any uncertainty about the diagnosis, percutaneous renal biopsy usually provides pathologic confirmation (Sánchez-Ortiz et al, 2004a). Most patients with renal metastases are managed with systemic therapy or placed on a palliative care pathway, depending on the clinical circumstances. Nephrectomy is almost never required except in extenuating circumstances, such as renal hemorrhage that is refractory to embolization. Patients with a solitary, strongly enhancing renal lesion and a history of organ-confined, nonrenal malignant disease are more likely to have RCC, particularly if the interval between the two diagnoses is substantial. In one study involving 100 consecutive patients with a renal mass and a history of nonrenal malignancy, none of the 54 patients without other evidence of disease progression had a renal metastasis (Rybicki et al, 2003; Sánchez-Ortiz et al, 2004a).

Other Malignant Tumors of the Kidney

Other malignant tumors of the kidney include adult Wilms tumor and neuroendocrine tumors such as renal carcinoid, small cell carcinoma, and primitive neuroectodermal tumor (PNET). All are relatively uncommon, but each has distinct tumor biology.

Carcinoid tumors arise from neuroendocrine cells, which are not normally present in the kidney (Romero et al, 2006). This is thus a rare renal malignant neoplasm with fewer than 60 cases reported in the English literature (Hansel et al, 2007; Lane et al, 2007b; Canacci and MacLennan, 2008). An association with horseshoe kidneys has been reported, with previous studies showing an increased relative risk of 82-fold compared with normal kidneys (Begin et al, 1998; Romero et al, 2006). Carcinoid tumors stain positive for markers of neuroendocrine tissue such as neuron-specific enolase and chromogranin (Lane et al, 2007b). Measurement of urinary or plasma serotonin or its metabolites can be diagnostic (Kulke and Mayer, 1999). Only a minority of patients will present with the carcinoid syndrome—episodic flushing, wheezing, and diarrhea (Jensen and Doherty, 2001; Romero et al, 2006; Lane et al, 2007b). Median age at diagnosis is 49 years (Romero et al, 2006). CT findings are nonspecific, and many renal carcinoids are small and nonaggressive. However, in a review of renal carcinoids, metastases were found in 46% of patients at diagnosis (Romero et al, 2006). Surgical excision is the mainstay of treatment (Kawajiri et al, 2004). Nephron-sparing surgery is preferred if the diagnosis is suspected preoperatively. Prognosis is good, particularly when associated with a horseshoe kidney (Begin et al, 1998; Lowrance et al, 2006). Significant adverse prognostic factors include age older than 40 years, tumor size greater than 4 cm, high mitotic rate, purely solid gross morphology, metastasis at initial diagnosis, and tumor extending through the renal capsule (Romero et al, 2006).

Other neuroendocrine tumors, including small cell carcinoma and large cell neuroendocrine carcinoma, can occur in the kidney but are even less common than renal carcinoids (Gonzalez-Lois et al, 2001; Majhail et al, 2003; Lane et al, 2007b). Approximately 30 cases of small cell carcinoma of the kidney have been reported for which another primary site could not be identified (Gonzalez-Lois et al, 2001; Kilicarsalan Akkaya et al, 2003; Mirza and Shahab, 2007). On pathologic examination, small cell carcinoma has

features of neuroendocrine and epithelial neoplasms and must be differentiated from Wilms tumor, PNET, lymphoma, and metastasis from pulmonary small cell carcinoma. Positive staining for neuron-specific enolase, chromogranin, and synaptophysin is characteristic (Kilicarsalan Akkaya et al, 2003). Preoperative differentiation from RCC is difficult, although a relatively hypovascular pattern may be an indication. Many small cell carcinomas of the kidney are locally advanced or metastatic at presentation, and flank pain or hematuria is common. Multimodal therapy with nephrectomy or tumor debulking combined with platinum-based chemotherapy regimens is advocated for extrapulmonary small cell carcinoma in general and may also be useful for the renal manifestation of this malignant neoplasm (Majhail et al, 2003; Mirza and Shahab, 2007). Long-term survivors are rare, and new treatment regimens are needed.

PNET is related to the Ewing sarcoma family of tumors that are more common in the pediatric population, typically manifesting in the bone or soft tissues of the extremities, trunk, and head and neck and only rarely in the viscera or kidneys (Jimenez et al, 2002; Maly et al, 2004; Bartholow and Parwani, 2012). However, all ages may be affected and several cases of PNET have been reported in the kidneys of adults (Karnes et al, 2000; Doerfler et al, 2001; Pomara et al, 2004; Thyaviahally et al, 2008). These tumors are derived from primitive neural crest cells, and positive staining for CD99 in addition to vimentin, cytokeratin, and neuron-specific enolase strongly supports the diagnosis (Conlusen et al, 2001; Ginsberg et al, 2002; Maly et al, 2004; Ellinger et al, 2006). On microscopic examination, renal PNET typically shows small round cells that may form characteristic Homer-Wright rosettes (Pomara et al, 2004; Thyaviahally et al, 2008). A characteristic t(11;22)(q24;q12) translocation is highly specific for PNET and can help differentiate it from neuroblastoma or adult Wilms tumor (Parham et al, 2001; Jimenez et al, 2002). Clinical symptoms are nonspecific; CT often demonstrates a heterogeneous ill-defined mass with areas of necrosis, and equivocal enhancement with contrast medium is typical (Doerfler et al, 2001). Renal PNET appears to behave more aggressively than similar tumors at other sites, exhibiting a strong propensity for local recurrence and early metastasis to lymph nodes, lung, liver, and bone (Conlusen et al, 2001; Parham et al, 2001; Thyaviahally et al, 2008). Multimodal treatment protocols combining tumor debulking, chemotherapy targeted to round cell or Ewing's family of tumors, and radiotherapy to the renal bed are often employed, but prognosis is poor, with overall 5-year disease-free survival of 45% to 55% (Casella et al, 2001; Ellinger et al, 2006; Thyaviahally et al, 2008).

Wilms tumor is the most common abdominal malignant neoplasm in children, but 3% of Wilms tumors are seen in adults. Of these, 20% are found between the ages of 15 and 20 years and the remaining 80% are distributed between the third and seventh decades of life (Winter et al, 1996). Adult and pediatric Wilms tumors are histologically similar with a distinctive triphasic pattern consisting of varying amounts of blastema, epithelium, and stroma (Orditura et al, 1997). Pathologic staging is the same as for pediatric Wilms tumor. Adult Wilms tumor typically presents as a heterogeneous intrarenal mass on CT with a relatively hypovascular pattern. Differentiation from RCC can be difficult if not impossible in many cases (Winter et al, 1996; Reinhard et al, 2004). Clinical presentation of adult Wilms tumor is also similar to that of RCC, and this tends to be an unsuspected pathologic diagnosis in most cases. Multimodal therapy should be considered, analogous to the treatment protocols for pediatric Wilms tumor (Neville and Ritchey, 2000; Firoozi and Kogan, 2003; Terenziani et al, 2004). Prognosis is worse for adults with Wilms tumor than for children with this malignant neoplasm because adults are more likely to present with advanced disease and a sudden drop in performance status (Winter et al, 1996).

BASIC AND CLINICAL BIOLOGY

An upper tract urothelial cancer (UTUC) is essentially any neoplastic growth of urothelium from renal calices to distal ureter. Although these tumors share similarities with urothelial cancers of the bladder and most data have been extrapolated from the latter, there are innate differences between these two neoplastic processes that warrant consideration when counseling patients about their disease and making treatment decisions. These anatomic and molecular differences are explored further in this chapter.

EPIDEMIOLOGY

Incidence and Mortality Rates

Upper urinary tract carcinoma is a relatively rare disease, comprising 5% to 10% of all urothelial tumors (Siegel et al, 2013), with highest incidences occurring in Balkan countries, where these cancers represent 40% of all renal neoplasms (Grollman, 2013). The peak incidence occurs in individuals in their 70s and 80s, and the disease occurs in up to 2 per 100,000 per year in Western countries (Roupret et al, 2011). Most occurrences are in a single renal unit, and synchronous bilateral urothelial upper tract tumors are rare (about 1.6%) (Holmång and Johansson, 2004). Metachronous occurrences are 80% after bladder cancer and 2% to 6% after contralateral kidney UTUC (Novara et al, 2009; Li et al, 2010). Most of these occur in the renal pelvis, followed by the ureter. **The frequency of urothelial tumors of the upper tract is increasing** (McCarron et al, 1982; Richie, 1988; Williams, 1991; Herr, 1998; Munoz and Ellison, 2000; David et al, 2009). An evaluation of the data from 1973 to 2005 using the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database showed increase in the annual incidence rates from 1.88 to 2.06 cases per 100,000 person-years (Raman et al, 2010). This change came mostly from ureteral neoplasms (0.69 to 0.91); the incidence of renal pelvis neoplasms had slightly decreased during the studied period (1.19 to 1.15). There was an observed trend toward earlier diagnosis of neoplasms, as the proportion of earlier-stage tumors increased from 7.2% in 1973 to 1984 to 31% in 1994 to 2005. This trend was also confirmed by data from the National Cancer Data Base (NCDB) for the United States for the years 1993 to 2005 (David et al, 2009). Although the authors reported a significant increase in high-grade tumors in both the renal pelvis and the ureter, the percentage of early-stage tumors also increased for each of the sites. Worse survival has been associated with increasing age, male gender, black non-Hispanic race, and

advanced tumor stage (Raman et al, 2010). Another series analyzing SEER data from 1973 to 1996 showed 5-year disease-specific survival rates of 75% overall and 95%, 88.9%, 62.5%, and 16.5% for in situ, localized, regional, and distant disease, respectively.

Variations by Gender, Race, and Age

Unlike the 4:1 ratio of presentation of bladder cancer in men to women, UTUC develops in men twice as frequently as in women (Greenlee et al, 2000; Lughezzani et al, 2010b). In addition, whites are about twice as likely as African-Americans to develop upper tract tumors (Greenlee et al, 2000). Even though some reports suggest that disease-specific annual mortality is greater in black men than in white men (7.4% vs. 4.9%) and greater in women than in men (6.1% vs. 4.4%) (Munoz and Ellison 2000), two recent multicenter studies (Fernández et al, 2009; Shariat et al, 2011) found lack of association between pathologic features or survival based on gender. Another study revealed no gender difference in disease-specific mortality after radical nephroureterectomy when clinicopathologic features were controlled for (hazard ratio [HR] 1.07, $P = .4$). It is interesting to note that in this study, female gender was associated with advanced stage (pT3) (odds ratio [OR] 1.15, $P = .03$) (Lughezzani et al, 2010b). In general, patients with upper tract cancer are older than patients with bladder tumors (Melamed and Reuter, 1993). Presentation in a patient younger than 60 years should raise the flag of hereditary UTUC as part of the Lynch syndrome spectrum of malignancies (Audenet et al, 2012). As discussed later in prognostic factors, advanced age may portend a worse cancer-specific prognosis. (Audenet et al, 2012).

ETIOLOGY

Genetic

Hereditary UTUC is associated with hereditary nonpolyposis colorectal carcinoma (HNPCC), or Lynch syndrome (Lynch et al, 1990). Patients with this syndrome have mutations in the DNA mismatch repair genes *MLH1*, *MSH2*, *MSH6*, and *PMS2* and may develop colonic, urothelial, gastric, pancreatic, uterine, sebaceous, and ovarian carcinomas. The associated urothelial cancers mainly arise in the upper tract, and it is unclear if carriers of these mutations may also have a higher risk of bladder malignancy (van der Post et al, 2010; Skeldon et al, 2013) or if this is a result of seeding of the bladder from the upper tract. Unlike with nonhereditary cancers, these patients are typically younger (mean age 55 years)

and are more likely to be female (Lynch et al, 1990). Besides the young age at presentation, presence of either a personal history or having two first-degree relatives with an HNPCC-associated cancer (particularly colon and endometrial) should raise suspicion for a hereditary component, and these patients are advised to undergo tissue evaluation for microsatellite instability or formal genetic testing if normal and tumor tissues are not available (Roupret et al, 2008; Acher et al, 2010; Audenet et al, 2012).

External Risk Factors

Aristolochic Acid Nephropathy

Several studies have suggested that aristolochic acid, which is found in plants *Aristolochia fangchi* and *Aristolochia clematitis*, has a mutagenic action on codon 139 of p53 gene. This mutation is predominant in patients with Balkan endemic nephropathy (BEN) and Chinese herb nephropathy. BEN is characterized by a degenerative interstitial nephropathy occurring in Balkan countries where these plants are endemic and grow as weeds in wheat fields (Grollman et al, 2007). It has a familial, but not inherited pattern, and incidence has been declining over the past 20 years (Stefanovic et al, 2008). The role of dietary exposure to aristolochic acid in BEN is supported by the fact that the family members who leave home early in life may not be affected (Radovanovic et al, 1985). Affected families display a much higher incidence of UTUC, but not bladder cancer (Petkovic, 1975). Tumors are usually of low grade and are more frequently multiple and bilateral than are UTUCs with other causes. Poorer outcomes are still seen in women (HR 2.2), with tumor size larger than 3 cm (HR 2.8), and with stage T3 or T4 disease (HR 3.1) (Dragicevic et al, 2007). The term *Chinese herb nephropathy* appeared after more than 100 patients in Belgium developed end-stage renal failure after consumption of Chinese herbal products that contained *A. fangchi*, and about half of whom developed UTUC with histologic features and genetic hallmarks identical to those of BEN (Cosyns et al, 1999; Nortier et al, 2000). The very high prevalence of UTUC in Taiwan and China is suspected to be in large part a result of the use of *Aristolochia* in various herbal remedies.

Smoking

Cigarette smoking appears to be the most important of the modifiable risk factors for UTUC and has been linked to generation of aromatic amines, which are metabolized into highly carcinogenic *N*-hydroxylamine. Individual susceptibility to effects of smoke may be linked to genetic polymorphisms in enzymes that neutralize this substance (Hung et al, 2004). This risk is dose related, ranging from OR 2.0 for a smoking history of 20 pack-years or less versus 6.2 for 60 or more. Observation suggests that smoking cessation offers the benefit of decreased risk (OR 2.3 for former vs. 4.4 current smokers). In addition, the risk from smoking seems more often to lead to ureteral rather than to renal pelvic tumors (McLaughlin et al, 1992).

Coffee

There have been reports of increased incidence of urothelial cancers with consumption of coffee (Ross et al, 1989); however, this relationship is confounded by smoking among habitual coffee drinkers (Villanueva et al, 2009). Recently, a study of 233,236 subjects in the European Prospective Investigation into Cancer and Nutrition with a mean follow-up of 9.3 years failed to establish association between risk of urothelial cancer and intake of water, coffee, tea, and dairy beverages (Ros et al, 2011).

Analgesics

Analgesic abuse is a well-documented risk factor associated with the development of UTUC (Johansson et al, 1974; Morrison, 1984; McCredie et al, 1986). In one study, 22% of patients with renal pelvic tumors and 11% of patients with ureteral tumors reported a

history of analgesic abuse with a latency period of approximately 2 years (Steffens and Nagel, 1988). Although phenacetin is the most well described causative agent in analgesic nephropathy, most patients have reported taking combination preparations that included caffeine, codeine, acetaminophen, and aspirin or other salicylates (De Broe and Elseviers, 1998). Histologic findings associated with analgesic abuse include thickening of the basement membrane (pathognomonic) and papillary scarring. Thickening of the basement membrane has been demonstrated in 15% of patients with UTUC and should alert the physician to the presence of analgesic abuse and the subsequent risk of contralateral involvement (Palvio et al, 1987). The degree of papillary scarring also appears to be closely related to tumor grade, although not with the development of squamous metaplasia or squamous cancer. Experimental evidence supports phenacetin-induced papillary necrosis as a cofactor in renal failure and carcinogenesis (Stewart et al, 1999). As phenacetin was replaced by its nontoxic metabolite paracetamol (acetaminophen), considering the long latent period of more than 20 years between the analgesic use and appearance of UTUC, the number of these cases has declined.

Arsenic

Excess inorganic arsenic in drinking water from artesian wells is a major health hazard in certain parts of the world and is associated with an increased risk of UTUC in addition to other diseases (Yang et al, 2002; Tan et al, 2008). Chronic exposure to arsenic in southwestern Taiwan has long been associated with a form of peripheral vascular disease known as *blackfoot disease* that causes dry gangrene of the extremities. This corresponds to a disproportionately increased rate of UTUC among urothelial cancers (20% to 25%) in this area. In addition to the fact that in these patients tumors in the ureter are twice as common as renal pelvic tumors, they behave in a similar fashion to other upper urinary tract tumors of similar grade and stage. There is a 1:2 male-to-female ratio of the upper tract tumors seen in Taiwan in contrast to the male predominance seen in all other areas of the world, which may be a result of higher exposure of women to arsenic fumes during cooking by steam heat over boiling water. If this is correct, it implies an inhalation risk as well as the risk of ingestion from drinking water with high arsenic content.

Occupation

A significantly increased risk for UTUC has been reported for persons with exposure to aromatic hydrocarbons, especially those used in chemical, petroleum, and plastic industries (risk ratio [RR] 4); patients with exposure to coal or coke (RR 4); and patients with exposure to asphalt or tar (RR 5.5) (Jensen et al, 1988). Aromatic amines account for carcinogenicity of β -naphthylamine and benzidine, both of which have been banned in most countries. In addition, chlorinated solvents used in metallurgy and printing have been implicated in the etiology of UTUC (OR 1.8). For these occupational hazards, both the type (contact or vapor inhalation) and duration of exposure (average 7 years) as causative agents are important, and the tumors can occur at long intervals (20 years) after exposure (Colin et al, 2009).

Chronic Inflammation, Infection, or Iatrogenesis

The development of squamous cell cancer (and less commonly adenocarcinoma) has been shown to be related to chronic bacterial infection associated with urinary stones and obstruction (Codec and Murrah, 1985; Spires et al, 1993). In addition, exposure to alkylating chemotherapy, such as cyclophosphamide and ifosfamide, also appears to confer an increased risk (RR 3.2) via production of acrolein metabolite (McDougal et al, 1981; Brenner and Schellhammer, 1987). Habitual daily use of anthranoid and chemical laxatives for more than 1 year has been associated with a ninefold risk of developing UTUC, but the carcinogenic mechanism is unclear (Pommer et al, 1999).

NATURAL HISTORY

Origins and Patterns of Recurrence

UTUCs are often associated with a poor prognosis. Up to 19% of patients with UTUC have been reported to have metastatic disease on initial presentation (Akaza et al, 1970). However, recent multicenter studies have suggested that although UTUCs are more often invasive and poorly differentiated than bladder cancers, in pathologically matched cohorts cancer-specific outcomes occur with equal frequency among patients with upper and lower tract (bladder) urothelial cancers (Catto et al, 2007; Moussa et al, 2010). In the cohort of patients with bladder and UTUC who were treated with radical cystectomy or nephroureterectomy, on direct comparison of the subset of patients with pathologic T1 or less or T4 disease, the location of neoplasm predicted survival (Rink et al, 2012a). In the cohort of patients with pT1 or less, this difference was partly attributed to aggressive features in the non-muscle-invasive bladder carcinoma, prompting radical cystectomy and technical limitations of upper tract sampling, necessitating early nephroureterectomy for patients with earlier stages of disease; and in the pT4 cohort, this may have been a result of a large proportion of patients with prostatic stromal invasion in the bladder cancer group, which still allows for complete excision of tumor with radical cystoprostatectomy (Green et al, 2013).

Ureter versus Renal Collecting System

Ureteral tumors occur more commonly in the lower than in the upper ureter. Overall, about 70% of ureteral tumors occur in the distal ureter, 25% in the mid-ureter, and 5% in the proximal ureter (Anderstrom et al, 1989; Messing and Catalona, 1998). This phenomenon may be a reflection of downstream implantation. One area of consensus is that removal of the entire ureter is mandatory when upper urinary tract cancers are removed by nephroureterectomy. Bilateral involvement (either synchronous or metachronous) occurs in 1.6% to 6.0% of sporadic UTUC (Babaian and Johnson, 1980; Murphy et al, 1981; Kang et al, 2003). There is no consensus on whether primary location of UTUC affects the cancer-specific mortality. Some studies show that even though ureteral location of cancer confers increased risk of advanced-stage at nephroureterectomy (Margulis et al, 2010), this does not translate into poor survival (Margulis et al, 2010; Raman et al, 2010). Other studies have shown that ureteral location of UTUC predicts recurrence and cancer-specific survival when compared with pelvicalyceal location (Park et al, 2004; Yafi et al, 2012). However, most of the authors agree that tumor grade and stage, along with lymphovascular invasion (LVI) and lymph node spread, trump the location in predicting cancer-related outcomes (Favaretto et al, 2010; Raman et al, 2010; Cha et al, 2012; Yafi et al, 2012). In one series, 5-year survival was 100% for Ta and Tis, 91.7% for T1, 72.6% for T2, and 40.5% for T3 tumors. Multivariate analysis in this series showed that tumor stage ($P = .0001$) and age of the patient ($P = .042$) were the only statistically significant predictors of survival (Hall et al, 1998a).

Chronology of Bladder and Upper Tract Urothelial Carcinomas

Upper Urinary Tract Tumors after Known Bladder Cancer

Particular insight into the contemporary risk for UTUC after treatment of bladder cancer is provided in several large series (Oldbring et al, 1989; Solsona et al, 1997; Herr, 1998; Rabbani et al, 2001; Mullerad et al, 2004; Sved et al, 2004; Canales et al, 2006; Tran et al, 2008; Wright et al, 2009). UTUCs have traditionally been reported to develop in 2% to 4% of patients with bladder cancer, with interval to recurrence ranging from 17 to 170 months, although higher rates up to 25% have been reported (Herr et al, 1996; Solsona et al, 1997). This discrepancy in numbers may be the result

of selection of patients, with more high-grade and dysplastic tumors reported in these series.

On the basis of SEER data from 1973 to 1996, UTUC developed in 657 of 91,245 patients with bladder cancer with a median follow-up of 4.1 years (Rabbani et al, 2001). The relative risk for white men and women was 64.2% and 75.4% at or before 2 years, 44.3% and 40.5% at 2 to 5 years, 50.8% and 42.1% at 5 to 10 years, and 43.2% and 22.2% at more than 10 years, respectively. These authors concluded that the incidence of UTUC is stable on long-term follow-up and that upper tract surveillance must remain rigorous for an extended period. The incidence of upper tract recurrence has been shown to be higher in patients with carcinoma in situ (CIS) than in patients with noninvasive papillary urothelial cancers and in patients treated with cystectomy for CIS rather than for invasive cancer (Solsona et al, 1997; Slaton et al, 1999; Canales et al, 2006). In another study of patients with bladder cancer, upper urinary tract recurrence was more likely to occur in patients with T1 versus Ta disease (HR 1.16), those with high-grade bladder cancer (HR 2.16), and patients with trigonal or periureteral presentation (HR 1.76) (Wright et al, 2009). On pathologic evaluation, recurrence was most likely to be superficial (Ta, T1, Tis) and to occur in the distal ureter only (47%). However, this finding has not been reported in all series. Earlier studies showed that in patients with Ta, T1, and Tis bladder cancers treated with bacille Calmette-Guérin (BCG), there was a 21% upper tract recurrence rate after a median interval of 7.3 years; the majority of tumors were invasive, and 38.8% of patients with recurrence died of their upper urinary tract disease (Herr et al, 1996).

In a recent meta-analysis of 27 studies with 13,185 participants who underwent cystectomy for bladder cancer, low-grade tumors, non-muscle invasive tumors, presence of CIS, multiple urothelial recurrences, multifocal tumors, history of previous UTUC, positive ureteral margin, N0 status, and involvement of male prostatic urethra or female urethra conferred increased risk of development of subsequent UTUC (Picozzi et al, 2012). Some of these factors (low grade, N0 stage, prostatic stromal vs. urethral involvement) were attributed to inferior patient survival in the presence of these adverse features. The type of urinary diversion did not show difference; however, it was assumed that the patients with continent diversion had more favorable disease features, hence introducing a selection bias in this cohort. Because there is no set protocol for UTUC surveillance after bladder cancer, follow-up schedule varied, and the majority of recurrences were diagnosed by symptoms, prevalently hematuria. Recurrences were mostly detected in the advanced or metastatic state, resulting in poor disease-specific survival (Picozzi et al, 2012). Sved and colleagues (2004) reported upper tract tumors in 2% of patients (5 of 235) observed for a mean of 42 months after radical cystectomy for bladder cancer. Upper tract tumor was diagnosed at a mean follow-up of 39.6 months, because of hematuria in four patients, and on routine intravenous urography in the remaining patient. Presence of a tumor in the prostatic urethra of the cystectomy specimen, which may be a predictor of a higher risk of multifocal disease, was the only initial tumor feature that was associated with a higher risk of subsequent upper tract tumor. Canales and coworkers (2006) found that patients with two or more stage Ta bladder cancer recurrences within 12 months were at increased risk for upper tract tumors and that surveillance of the upper tracts is indicated. In addition, presence of ureteral reflux and bladder cancers arising close to a ureteral orifice have also been shown to predispose to UTUC (Zincke et al, 1984; Herr et al, 1992; Hudson and Herr, 1995).

Delayed recurrence is more common in the ureter than in the renal pelvis and appears to occur earlier (at 40 vs. 67 months). In patients treated with BCG for CIS of the bladder, upper urinary tract cancer is even more common (about 30% of cases) and appears to occur distally (in the distal, juxtavesical, and intramural portions of the ureter), especially in patients subjected to cystectomy whose disease is refractory to BCG. Therefore, in cases of high-risk bladder cancer (high-grade T1 disease or CIS), at least imaging of the upper urinary tract should be performed annually as part of routine follow-up (Herr et al, 1996).

Bladder Recurrence after Upper Urinary Tract Tumors

Patients with upper urinary tract tumors are at risk for development of bladder cancer, with an estimated incidence that varies in multiple reports from 15% to 75% within 5 years of the development of the upper tract cancer (Kakizoe et al, 1980; Huben et al, 1988; Anderstrom et al, 1989; Hisataki et al, 2000; Miyake et al, 2000; Kang et al, 2003). This high incidence of metachronous bladder involvement suggests that routine bladder surveillance should be performed. Why do bladder cancers follow upper tract cancers more often than bladder cancers are followed by upper tract cancers? Theories include downstream seeding, longer exposure time to carcinogens in the bladder, and greater number of urothelial cells in the bladder that are subject to random carcinogenic events. Many would agree that most recurrences downstream are caused by seeding. This is supported by the monoclonal nature of the bladder tumor recurrences (Junker et al, 2005), and the pattern of recurrence especially after nephroureterectomy. Most recurrences in the bladder occur within 2 years and are usually at the sites of bladder trauma during total ureterectomy (Kang et al, 2003). It is interesting to note that renal insufficiency is associated with a higher risk of contralateral upper tract tumor.

Studies have suggested that in rapidly recurrent high-grade cancers, specific gene mutations are also demonstrated in subsequent bladder cancers (Harris and Neal, 1992; Lunec et al, 1992; Habuchi et al, 1993). Association of a higher bladder tumor incidence after upper tract tumor multifocality supports a role of distal seeding (Matsui et al, 2005). In contrast, microsatellite studies in low-grade UTUCs, which tend to recur less rapidly in the bladder, have suggested genetic discordance between these upper tract tumors and subsequent bladder cancers in 46% of cases (Takahashi et al, 2000), supporting a field effect (Takahashi et al, 2001). The paradoxical finding that the risk of subsequent bladder tumor is inversely related to upper tract tumor size and stage may reflect a higher and earlier risk of death from the primary tumor in these cases. In the reports by Hisataki and coworkers (2000), Matsui and associates (2005), and Terakawa and colleagues (2008), increased upper tract tumor stage at the time of nephroureterectomy correlated with a higher risk for subsequent bladder tumor. In a recent European multicenter study reported by Novara and coworkers (2009), prior bladder tumor before upper tract tumor was the only independent risk factor for bladder tumor after nephroureterectomy in multivariate analysis. Raman and associates (2007) reported that the grade, but not the stage, of the prior upper tract tumors correlated with the pathologic findings of the subsequent bladder tumors.

Association with Carcinoma in Situ

As would be expected, the risk of bilateral disease and multifocality increases with the presence of CIS. The risk of bilateral disease is around 3% to 5% overall but can be as high as 25% when there is associated CIS of the bladder (Herr et al, 1996). In addition, these patients are at higher risk for subsequent panurothelial disease. In such cases, management should take into account the high probability that there will be multifocal disease. This approach should include a conservative approach when feasible and frequent follow-up of bladder and extravesical sites such as prostatic urethra and upper urinary tracts.

Dissemination of Disease

Urothelial carcinoma of the upper urinary tract may spread via direct invasion into the renal parenchyma or surrounding structures, lymphatic or hematogenous invasion, and epithelial spread by seeding or direct extension. It is clear that high-grade tumors demonstrate a greater propensity to invade and that non-organ-confined disease (>pT2) is the most significant predictor of the development of metastases (95%), followed by vascular invasion (83%) and lymphatic invasion (77%) (Davis et al, 1987; Margulis et al, 2009).

Lymphatic

Depending on the location of the tumor in the renal pelvis, upper or lower two thirds of the ureter, lymphatic spread from the upper urinary tract extends to the renal hilar, para-aortic, paracaval, inter-aortocaval, and ipsilateral common iliac and pelvic lymph nodes (Batata and Grabstald, 1976; Kondo et al, 2007). This extension is directly related to the depth of invasion of the primary tumor.

Hematogenous

The most common sites of hematogenous metastases from upper tract tumors are the liver, lung, and bone (Batata et al, 1975; Brown et al, 2006). Although it is very rare, direct extension into the renal veins and vena cava may occur in renal pelvic tumors (Jitsukawa et al, 1985; Geiger et al, 1986).

Epithelial

Spatially distinct synchronous and metachronous tumors have prompted the rise of two theories of their origin. Monoclonal theory explains the epithelial spread of the tumors via urinary seeding and/or intraepithelial migration of malignant cells (Harris and Neal, 1992), and these multiple tumors are then the descendants of single genetically modified neoplastic cells. Epithelial spreading may occur in both antegrade and retrograde manners. Antegrade seeding is more common and thought to be the most likely explanation for the high incidence of recurrence in patients in whom a ureteral stump is left in situ after nephrectomy and incomplete ureterectomy (Johnson and Babaian, 1979). In contrast, the "field effect" theory assumes the propensity of urothelium to diffusely form unrelated de novo tumors as a result of exposure to a mutagenic environment. It seems that a small but significant proportion of multifocal cancers are, in fact, derived from different clones (Hafner et al, 2002). Not excluding the idea of molecular evolution of the tumors arising from a single clone, the dual pattern of molecular evidence currently supports the view that urothelial tumors can develop monoclonally through epithelial intraluminal dissemination of tumor cells and field "cancerization."

Panurothelial Disease

Panurothelial disease is defined as a disease involving the bladder as well as two extravesical sites. In males, this could include one or both upper urinary tracts and/or the prostatic urethra, and in females the bladder and both upper urinary tracts. The low frequency of panurothelial disease and the lack of prospective studies do not permit absolute conclusions about treatment impact and outcomes. Solsona and colleagues (2002) described their experience with panurothelial disease. In this cohort of 35 patients, the population most at risk was those with high-risk superficial bladder multifocal tumors and those with associated bladder CIS. The approach of these researchers was cystectomy for high-grade and any invasive disease, and management of the upper tracts was largely conservative with local resection and treatments for noninfiltrating tumors and radical excision with more aggressive tumors. These patients, however, present a large clinical dilemma, as the only curative approach would be a total removal of the genitourinary tract.

More recently, Nguyen and colleagues (2014) described their experience with panurothelial disease. They identified 35 patients with histologically proven urothelial carcinoma of the bladder and both upper urinary tracts. The average follow-up was 95 months. They identified two distinct groups: those with initial upper tract pathology in 17 and initial bladder pathology in 18 patients. They found there was no statistically significant difference between those who had bladder pathology first and those who had upper tract pathology first. Within that group there were 8 patients who originally had low-grade disease on presentation and subsequently transitioned to multifocal high-grade disease and tumor invasion and progression. Four of these patients who initially had multifocal

low-grade tumors rapidly progressed to high-grade tumors and metastatic disease and death. The demographics of this group were quite interesting: There was a similar distribution of men and women, and nearly half did not have a smoking history. Individual genetic factors may play a role in susceptibility of these patients, which is witnessed by the fact that most of these individuals had a history of another malignancy or a family history of cancer. These genetic alterations, if found, may provide a clue in identifying those patients who may benefit from total removal of urothelium.

This undoubtedly represents a very perplexing population of patients and difficult management problems. The role of systematic disease has not yet been established; however, most would agree that cystectomy is indicated for those with multifocal high-grade disease. In addition, there should be close surveillance of the upper tract for any infiltrating disease. In younger patients, it may be helpful to have early recognition of disease progression and early choice of total removal of the genitourinary system as a way of preventing progression to metastatic disease and potential death. Certainly, more studies are needed in this area.

HISTOPATHOLOGY

The majority of upper tract tumors are urothelial cancers. These are largely derived from transitional urothelium; squamous cell cancers and adenocarcinomas represent a small minority (Bennington et al, 1975; Vincente et al, 1995; Flanigan and Kim, 2004).

Normal Upper Tract Urothelium

Whereas the bladder is of endodermal origin, the ureter and renal pelvis are derived from the mesoderm. Nevertheless, the urothelial lining of the upper urinary tract closely approximates that of the bladder except for the markedly reduced thickness of the muscle layer and the abutting of the urothelium to the renal parenchyma proximally. The epithelial layer is continuous from the level of the calyces to the distal ureter. It has been postulated that the urothelial layer may even “extend” into the collecting ducts, raising the possibility that collecting duct renal cancers may be closely related to urothelial cancers and perhaps better treated by agents used for urothelial cancers (Orsola et al, 2005). This observation needs further confirmation.

Renal Pelvis and Calyces

The walls of the calyces and the pelvis contain fibrous connective tissue and two layers of smooth muscle and are lined on their inner surfaces with transitional epithelium (Dixon and Gosling, 1982) (Figs. 58-1 and 58-2). Thin muscle layers originate in the minor calyces and form a spiral, helical arrangement (Fig. 58-3).

Ureter

The ureter demonstrates two continuous thin muscle layers with a loosely spiraled internal layer and a more tightly spiraled external layer. In the lower third of the ureter, a third outer longitudinal layer is present. All three layers merge with the three layers (inner longitudinal, middle circular, and outer longitudinal) of the bladder wall, which run longitudinally, transversely, and obliquely. Beneath the outer muscle coat is the serosa, made up of loose connective tissue and containing blood vessels and lymphatics (Hanna et al, 1976; Notley, 1978) (Figs. 58-4 and 58-5).

Abnormal Urothelium

Metaplasia and Dysplasia

Several studies have suggested that UTUCs progress through histologic changes from hyperplasia to dysplasia to frank CIS in a significant proportion of patients (Heney et al, 1981; McCarron et al, 1982). CIS may be patchy and may extend proximally to the

Figure 58-1. Low-magnification view of a section through the kidney. The renal medulla ends in the pointed renal papilla. Urine empties into the Y-shaped space made up of the renal calyces (the arms of the Y) and the pelvis (the base of the Y).

Figure 58-2. This image shows several large collecting ducts near the end of a medullary pyramid (i.e., close to their opening into the pelvis). The transitional epithelium of the renal pelvis is continuous with that of the ureters and bladder.

collecting ducts of the kidney (Mahadevia et al, 1983). More severe urothelial dysplastic changes are associated with a greater risk for tumor recurrence in the distal ureter and bladder and a reduced prognosis.

Benign Lesions: Papillomas and von Brunn Nests

Papillomas and inverted papillomas are generally considered benign lesions; however, because of their association with either synchronous or metachronous upper tract urothelial tumors (Renfer

Figure 58-3. In this specimen from the renal pelvis the connective tissue immediately beneath the epithelium is inconspicuous, obscured by a layer of smooth muscle (note elongated nuclei). Beneath the smooth muscle is loose connective tissue, including conspicuous adipocytes.

Figure 58-4. A and B, Cross section of ureter. The ureter has an irregular lumen, which is lined by transitional epithelium. Under the epithelium is a connective tissue layer and, beneath that, three layers of smooth muscle: inner longitudinal, middle circular, and outer longitudinal. (A, © 1999, Rector & Visitors of the University of Virginia.)

et al, 1988; Stower et al, 1990; Chan et al, 1996; Cheville et al, 2000), they require close surveillance. One series demonstrated an 18% incidence of malignancy associated with inverted papilloma of the ureter (Grainger et al, 1990). Other studies have suggested that there are two types of urinary inverted papilloma. The lesions of type 1 behave in a benign fashion, whereas those of type 2 may have a malignant potential. Because there is currently no way to

Figure 58-5. Transitional epithelium and loose connective tissue that compose the mucosa of the urinary tract. Transitional epithelium superficially resembles nonkeratinized stratified squamous epithelium, but note that the epithelial cells nearest the apical (outer) surface are not flattened but cuboidal. Transitional epithelium is a stratified epithelium characterized by the fact that the most apical cells are the roundest and largest in diameter. It is designed to be able to increase its surface area as the lumen is dilated by urine. (© 1999, Rector & Visitors of the University of Virginia.)

distinguish between these two types, it has been advised that follow-up for all cases of inverted papilloma should be continued for at least 2 years after initial diagnosis (Asano et al, 2003). Similarly, these findings suggest that close surveillance of the upper tracts for malignancy is warranted when inverted papilloma is diagnosed.

Urothelial Histology

Urothelial carcinomas make up more than 90% of upper urinary tract tumors. They may manifest as flat (CIS), papillary or sessile lesions, and may be unifocal or multifocal. On histologic examination these lesions are similar to urothelial carcinoma of the bladder, but the relative thinness of the muscle layer of the renal pelvis and ureter makes invasion through the muscle coat an earlier event. CIS, as in the bladder, can be particularly difficult to identify and can vary in appearance from a whitish plaque to epithelial hyperplasia or a velvety red patch as a result of increased submucosal vascularity (Melamed and Reuter, 1993). Progression to muscle invasion or invasion into the renal parenchyma or adventitial tissues may occur and is more likely, given the relative thinness of the muscle coat of the upper tracts. Reported variants of urothelial carcinoma are squamous cell, glandular, sarcomatoid, micropapillary, neuroendocrine, and lymphoepithelial and can be seen in as high as 25% of UTUCs. Although all of these variants are considered aggressive tumors, some data show that with adjustment for the rest of clinicopathologic characteristics, variant histology has not been shown to predict poor clinical outcome (Rink et al, 2012b).

Micropapillary Variant. A micropapillary variant of urothelial carcinoma (MPUC) in the bladder is associated with aggressive behavior. This histologic subtype is very rare in the upper urinary tract, and most patients have advanced disease at presentation. Contrary to the study by Rink and colleagues, two studies (Holmäng et al, 2006; Sung et al, 2014) independently linked the micropapillary variant to inferior progression and cancer-free survival. Holmäng described 26 patients with this entity in the upper urinary tract. Twenty-two patients had stage T3 disease at presentation, and CIS or LVI was noted in 64% and 81% of patients, respectively. Five-year survival was only 26.9%, and overall the disease-specific mortality was 77%. In the multivariable model (Sung et al, 2014), MPUC still remained a statistically significant independent predictor for progression-free survival (HR 3.85, $P = .003$). MPUC was associated with poorer cancer-specific survival than non-MPUC ($P < .001$).

Nonurothelial Histology

Nonurothelial carcinomas of the upper tracts represent a wide spectrum of lesions, from benign to highly malignant. The most common of these are squamous cell cancers and adenocarcinomas.

Squamous Cell Cancers. Pure squamous cell cancers make up 0.7% to 7.0% of upper urinary tract cancers (Babaian and Johnson, 1980; Blacker et al, 1985). They are frequently associated with a condition of chronic inflammation or infection or with analgesic abuse (Stewart et al, 1999). These tumors occur six times more frequently in the renal pelvis than in the ureter and are typically moderately to poorly differentiated and more likely to be invasive at the time of presentation.

Adenocarcinomas. Adenocarcinomas account for less than 1% of all renal pelvic tumors and are typically associated with long-term obstruction, inflammation, or urinary calculi (Stein et al, 1988; Spire et al, 1993). These tumors typically are at an advanced stage on presentation and display a poor prognosis.

Other Miscellaneous Tumors. Fibroepithelial polyps (Musselman and Kay, 1986; Blank et al, 1987) and neurofibromas (Varela-Duran et al, 1987) are uncommon benign lesions that are typically treated by simple excision. Neuroendocrine (Ouzzane et al, 2011b) and hematopoietic (Igel et al, 1991) tumors and sarcomas (Coup, 1988; Madgar et al, 1988) have also been reported to involve the upper urinary tracts. Because of the rare nature of these tumors they are typically treated by excision with adjuvant therapy that is based on the experience with tumors of similar histology occurring elsewhere in the body.

DIAGNOSIS

The most common presenting sign of upper tract urothelial tumors is hematuria, either gross or microscopic. This occurs in 56% to 98% of patients (Murphy et al, 1981; Guinan et al, 1992a; Raabe et al, 1992). Flank pain is the second most common symptom, occurring in 30% of tumors. This pain is typically dull and believed to be secondary to a gradual onset of obstruction and hydronephrotic distention. In some patients, pain can be acute and can mimic renal colic, typically ascribed to the passage of clots that acutely obstruct the collecting system. These common symptoms of localized disease (hematuria, dysuria) and of advanced upper tract tumors (weight loss, fatigue, anemia, bone pain) are similar in type and frequency to those of bladder cancer. However, flank pain caused by obstruction by tumor or clot is more prevalent in upper tract tumors, having been reported in 10% to 40% of cases (Babaian and Johnson, 1980; McCarron et al, 1983; Richie, 1988; Williams, 1991; Melamed and Reuter, 1993). About 15% of patients are asymptomatic at presentation and are diagnosed when an incidental lesion is found on radiologic evaluation. Patients may also have symptoms of advanced disease, including flank or abdominal mass, weight loss, anorexia, and bone pain. Nearly all upper tract tumors are diagnosed during the patient's life, and therefore UTUC represents a rare autopsy finding (Resseguie et al, 1978).

Radiologic Evaluation

Although intravenous pyelography has been the traditional means for diagnosis of upper tract lesions, this has been supplanted by computed tomographic urography. Computed tomography (CT) is easier to perform and less labor intensive than intravenous pyelography. It also has a higher degree of accuracy in determining the presence of renal parenchymal lesions. Alleviating the concern for missing the small urinary filling defects (<5 mm) between the "cuts" of the traditional CT scan, a three-dimensional reconstruction of image of the upper tracts appears to be equal to intravenous pyelography in imaging the ureters and renal pelvis (McTavish et al, 2002). With CT urography, the sensitivity for detecting upper tract malignant disease has been reported to approach 100%, with a specificity of 60% and a negative predictive

value of 100% (Caoili et al, 2002). CT urography does, however, expose the patient to higher doses of radiation.

Radiolucent filling defects, obstruction or incomplete filling of a part of the upper tract, and nonvisualization of the collecting system are the typical findings suggestive of an upper urinary tract tumor. Identification of filling defects, which account for 50% to 75% of cases, typically requires the intravenous administration of contrast material (Murphy et al, 1981; Fein and McClennan, 1986). The differential diagnosis of these defects includes blood clot, stones, overlying bowel gas, external compression, sloughed papilla, and fungus ball. Stones can be ruled out most easily by confirmation of calcification by renal ultrasonography or CT. Urothelial cancers have an average density of 46 Hounsfield units (HU) and a range of 10 to 70 HU (Lantz and Hattery, 1984). This is in contrast to an average of 100 HU seen in radiolucent uric acid stones (range, 80 to 250 HU). Thus CT can be useful in distinguishing between these two common causes of radiolucent filling defect on excretory urography or retrograde ureterography. The impact of hydronephrosis and nonvisualization for renal pelvis tumors versus ureteral tumors as indicators of a higher stage is uncertain. Nonvisualization is reported in 20% of renal pelvis tumors, only 33% of which are invasive (McCarron et al, 1983). Nonvisualization is reported in 37% to 45% of ureteral tumors and carried a 60% risk of invasion in one series (McCarron et al, 1983). In other reports there is no correlation of nonvisualization and stage (Batata and Grabstald, 1976; Anderstrom et al, 1989). Hydronephrosis with or without an associated filling defect is linked with invasion in 80% of ureteral tumors (McCarron et al, 1983; Cho et al, 2007).

Radiolucent, noncalcified lesions may require additional evaluation by retrograde urography or ureteroscopy, with or without biopsy and cytology. Overall, retrograde urography has an accuracy of 75% in diagnosis of an upper tract malignant neoplasm (Murphy et al, 1981). An incompletely filled or obstructed renal infundibulum or calyx, occurring in 10% to 30% of cases, again typically requires retrograde urography or ureteroscopy to confirm the diagnosis.

Evaluation of the contralateral kidney is important not only because of possible bilaterality of the disease but also because it allows a determination of the functionality of the contralateral kidney. At times, a split-function renal scan may be helpful in determining the contribution of both the "diseased" and the presumed "normal" kidney to the patient's overall renal function.

Some have suggested that ultrasonography has sensitivity equal to that of urography in evaluating patients with painless gross hematuria for upper tract malignant disease (Yip et al, 1999; Data et al, 2002). For staging purposes, CT or magnetic resonance imaging (MRI) is most useful in determining the extent of invasion, an associated mass lesion outside the collecting system, and the presence of lymph node or distant metastases (Milestone et al, 1990). CT is also more sensitive than conventional radiography in determining minimally radiopaque substances, making it useful in identifying urine excreted by poorly functioning areas of kidney (as in obstructed areas) (Kenney and Stanley, 1987). The greatest downside of CT or MRI is in the detection of small lesions that may be lost in volume averaging in addition to poor sensitivity for assessment of invasion. In one series, CT predicted TNM stage in 60% of patients; it understaged 16% and overstaged 24% (Scolieri et al, 2000).

Cystoscopy

Because upper urinary tract tumors are often associated with bladder cancers, cystoscopy is mandatory in the evaluation to exclude coexistent bladder lesions.

Ureteroscopic Evaluation and Biopsy

The technical advances achieved in the realm of endoscopic equipment have made the flexible and rigid ureteroscope a key part of the evaluation (and treatment) of upper urinary tract tumors. **Diagnostic accuracy can be improved from approximately 75% with**

excretory or retrograde urography alone to 85% to 90% when it is combined with ureteroscopy (Stroom et al, 1986; Blute et al, 1989). Although pyelovenous and pyelolymphatic migration has been reported with ureteroscopy, this phenomenon appears to be uncommon and should not preclude its use (Lim et al, 1993).

As with bladder tumors, 55% to 75% of ureteral tumors are low grade and low stage (Cummings, 1980; Richie, 1988; Williams, 1991). Also, like bladder cancers, approximately 85% of renal pelvic tumors are papillary and the remainder sessile. Invasion of the lamina propria or muscle (stage T1 or T2) occurs in 50% of papillary and in more than 80% of sessile tumors. Overall, 50% to 60% of renal pelvic tumors are invasive into either the lamina propria or muscle. In ureteral tumors, invasion is also more common than in bladder tumors (Anderstrom et al, 1989; Williams, 1991).

In addition to visualization of the tumor, ureteroscopy allows more accurate biopsy of suspected areas, with either biopsy forceps or brushing. Despite reports of changes in grade or stage from diagnostic biopsy (Smith et al, 2011) to subsequent resection, reasonable histologic correlation (78% to 92%) between the ureteroscopic biopsy specimen and the final pathologic specimen has been established (Keeley et al, 1997c; Guarnizo et al, 2000; Brown et al, 2007). It appears that fresh samples obtained ureteroscopically provide the best chance of predicting eventual pathologic findings. In one study, a cell block from biopsy specimens was prepared when a visible tumor was present, and grades of ureteroscopic biopsy specimens were compared with grades and stages of surgical specimens in 42 cases. Of 30 low- or moderate-grade specimens, 27 (90%) proved to be low- or moderate-grade urothelial carcinoma; 11 of 12 high-grade specimens (92%) proved to be high-grade urothelial cancer, and 8 (67%) were invasive (T2 or T3) (Keeley et al, 1997c). In contrast, the urologist's impression of the tumor grade based on ureteroscopic appearance is likely to be correct in only 70% of cases, suggesting that biopsy is also needed to further define this important aspect of staging (El-Hakim et al, 2004).

Because of the small size and shallow depth of ureteroscopic biopsy specimens, a precise correlation with eventual tumor stage is difficult. Therefore, in predicting the tumor stage, a combination of the radiographic studies, the visualized appearance of the tumor, and the tumor grade provides the surgeon with the best estimation for risk stratification. In general, CIS of the upper tract is a presumptive diagnosis that is made by the presence of unequivocally positive selective cytology in the absence of any radiographic or endoscopic findings. The exception is when the diagnosis is made because of a ureteral CIS finding at cystectomy. Although, as stated earlier, grading of the tumors may be fairly accurate, staging is much more problematic. Of 40 urothelial tumors staged in one series (40% in the renal pelvis, 20% in the proximal ureter, and 40% in the distal ureter), ureteroscopic grade matched surgical grade in 78% of cases and was less than surgical grade in the remaining 22%. Lamina propria was present in 68% of biopsy specimens (62% of cup biopsies and 100% of loop biopsies), but tumors thought to be Ta were upstaged to T1 to T3 in 45% of cases at the time of complete resection of the lesion (Guarnizo et al, 2000). Therefore, accurate tumor grading on ureteroscopic biopsy may help in estimating tumor stage. In one series, a biopsy specimen showing grade 3 tumor accurately predicted tumor stage in more than 90% of cases (Skolarikos et al, 2003).

Is ureteroscopy (with or without biopsy) necessary in all cases of suspected upper tract tumors? No. In fact, ureteroscopy should probably be reserved for situations in which the diagnosis remains in question after conventional radiographic studies and for those patients in whom the treatment plan may be modified on the basis of the ureteroscopic findings, for example, endoscopic resection. Although there is no evidence that ureteroscopy diminishes the prognosis of a patient destined to proceed to nephroureterectomy, and although the risks of tumor seeding, extravasation, and dissemination are low in experienced hands, these risks are real and should preclude ureteroscopy when it is unnecessary (Hendin et al, 1999).

Antegrade Endoscopy

In some cases of upper tract tumors, percutaneous access to the renal pelvis may be required for diagnosis or treatment. In such cases, antegrade urography and ureteroscopy may be useful for tumor resection, biopsy, or simple visualization. Larger-caliber scopes that can be passed into the renal pelvis in this manner may be particularly helpful in resecting or debulking larger volumes of tumor in this area (Stroom et al, 1986; Blute et al, 1989). One must remember, however, that tumor cell implantation in the retroperitoneum and along the nephrostomy tube tract has been reported after these procedures (Tomera et al, 1982; Huang et al, 1995).

Role of Cytology and Other Tumor Markers

Urine cytology is a specific tool that is useful in the diagnosis of upper tract carcinomas. On the other hand, the sensitivity of cytology remains an issue. In general, the sensitivity of voided urine (or bladder wash) cytology is directly related to tumor grade. **Overall accuracy estimates of the sensitivity of cytology have ranged from about 20% for grade 1 tumors to 45% and 75% for grade 2 and grade 3 tumors, respectively** (Murphy and Soloway, 1982; Konety and Getzenberg, 2001).

Even if a voided cytology specimen is abnormal in a patient with an upper tract filling defect, one must be cautious in determining the site of origin of the malignant cells. Ureteral catheterization for collection of urine or washings may provide more accurate cytologic results. However, even in this setting, a substantial false-negative or false-positive result (22% to 35%) can be expected (Zincke et al, 1976). It would appear that saline washing provides a better cell yield and improves cytologic results secondary to the release by hydroscopic forces of loosely adherent cells from the urothelium. Still better accuracy can be achieved by brush biopsy through a retrograde catheter or ureteroscope. Sensitivity in the 90% range with specificity approaching 90% may be possible with these techniques (Stroom et al, 1986; Blute et al, 1989). Brush biopsies have, however, also been reported to result in severe complications, including massive hemorrhage and perforation of the urinary tract with extravasation (Blute et al, 1981).

It appears that the exposure of urothelial cells to ionic, high-osmolar contrast agents as in retrograde pyelography may worsen cytologic abnormalities. Thus, it is probably prudent to obtain cytologic specimens before the use of these agents (Terris, 2004).

Early results suggest that fluorescence in situ hybridization (FISH) also may be useful in the diagnosis of upper tract urothelial tumors. In a study of 21 consecutive upper urinary tract urothelial cancer patients and 10 healthy controls in which FISH probes were used for chromosomes 3, 7, 17, and the *CDKN2A* (9p21) gene, overall sensitivity of FISH was significantly higher than that of cytology and specificity for both was 100% (Luo et al, 2009). However, this small study has not yet been validated.

STAGING AND PROGNOSIS

Staging

The staging of upper urinary tract tumors parallels the staging of bladder tumors.

TNM Staging System

The TNM classification and staging system is the most commonly used. A comparison of the American Joint Committee on Cancer (AJCC) staging system and the TNM system is presented in Table 58-1.

The histologic characteristics and biology of upper tract tumors still affect treatment decisions, technologic improvements notwithstanding. The entity of benign papilloma, which responds favorably regardless of the extent of treatment, is well described in older series of upper tract tumors (Bloom et al, 1970; Batata and Grabstald, 1976). The existence of similar low-grade papillomas of low-grade

TABLE 58-1 American Joint Committee on Cancer (AJCC) and TNM Staging and Classification Systems for Upper Urinary Tract Tumors

PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor.
Ta	Papillary noninvasive carcinoma.
Tis	Carcinoma in situ.
T1	Tumor invades subepithelial connective tissue.
T2	Tumor invades the muscularis.
T3	Tumor invades periureteral fat (for renal pelvis only).
	Tumor invades beyond muscularis into perinephric fat or the renal parenchyma.
T4	Tumor invades adjacent organ or through the kidney into the perinephric fat.
LYMPH NODES (N)	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastases
N1	Metastasis to a single lymph node, 2 cm or less in greatest dimension.
N2	Metastasis in a single lymph node, more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph nodes, none more than 5 cm in greatest dimension.
N3	Metastasis in a lymph node, more than 5 cm in greatest dimension.
DISTANT METASTASIS (M)	
MX	Distant metastasis cannot be assessed.
M0	No distant metastasis.
M1	Distant metastasis.
AJCC STAGING SYSTEM	TNM CLASSIFICATION SYSTEM

IV	T4 or any T, N+, M+

malignant potential in the bladder remains controversial (Cheng et al, 1999; Cheng and Bostwick, 2000; Oyasu, 2000). It is unclear whether the differences between upper tract papillomas and bladder papillomas are biologic or semantic. Approximately 85% of renal pelvis tumors are papillary; the remainder are sessile. This distribution is similar to that of bladder tumors. However, the stage of upper tract tumors is T1 or T2 in approximately 50% of papillary and 80% of sessile lesions, respectively (Cummings, 1980; Richie, 1988; Williams, 1991). Thus, 50% to 60% of renal pelvis tumors are invasive, in contrast to most bladder tumors, which are noninvasive; 55% to 75% of ureteral tumors are low grade and low stage, but invasion is still more common than among bladder tumors (Anderstrom et al, 1989; Williams, 1991). Patients with upper urinary tract tumors are most often in the sixth or seventh decade of life on presentation and thus are usually older than patients with bladder tumors (Melamed and Reuter, 1993).

Tumors of the renal pelvis are slightly more common than ureteral tumors (Batata and Grabstald, 1976; Richie, 1988; Maulard-Durdax et al, 1996). Ureteral tumors occur in the distal, middle, and proximal segments in 70%, 25%, and 5% of cases, respectively (Babaian and Johnson, 1980; Anderstrom et al, 1989; Williams,

1991; Messing and Catalona, 1998). After conservative treatment, ipsilateral upper tract tumor recurrence is common in a proximal-to-distal direction and is seen in 33% to 55% of patients (Mazeman, 1976; Johnson and Babaian, 1979; Babaian and Johnson, 1980; Cummings, 1980; McCarron et al, 1983). Recurrence proximal to the original lesion is rare.

This high rate of ipsilateral recurrence results in part from a multifocal field change, which is even more pronounced than in bladder cancer. Areas of atypia, dysplasia, or CIS are reported in 60% to 95% of specimens after nephroureterectomy for renal pelvis tumor (Johansson et al, 1976; Kakizoe et al, 1980; Heney et al, 1981; Nocks et al, 1982; McCarron et al, 1983; Melamed and Reuter, 1993). Molecular techniques demonstrate that downward seeding of tumor accounts for some recurrences (Harris and Neal, 1992).

Metachronous bilateral upper tract tumors are rare. In a review of all 768 cases of upper tract tumor reported in western Sweden from 1971 to 1998, the rate of metachronous bilateral tumors was 3.1% and was associated with increased age and short survival time after the event (Holmäng and Johansson, 2006).

The occurrence of bladder tumors after upper tract tumors, and vice versa, is another expression of the field change, multifocal risk that affects initial treatment decisions. CIS is present in the distal ureter at the time of cystectomy in 7% to 25% of cases (Melamed and Reuter, 1993; Solsona et al, 1997; Herr, 1998); 15% to 50% of all cases of upper tract tumor occur in patients with a history of bladder tumor (Batata and Grabstald, 1976; Babaian and Johnson, 1980). The incidence of upper tract tumor after bladder tumor is 2% to 4% with a mean time to occurrence of 70 months (Shinka et al, 1988; Oldbring et al, 1989; Melamed and Reuter, 1993; Herr et al, 1996). Upper tract tumors are reported in 3% to 9% of patients after cystectomy for bladder cancer in older series (Zincke and Neves, 1984; Mufti et al, 1988).

Three particular forms of upper tract urothelial tumors, two associated with environmental exposure (aristolochic acid nephropathy, which includes Balkan and Chinese herbal nephropathy, as well as those seen in arsenic-endemic regions), analgesic abuse, and those associated with Lynch syndrome, have an even higher tendency to multiple and bilateral recurrences than do sporadic tumors (Markovic, 1972; Petkovic, 1975; Mahoney et al, 1977; Johansson and Wahlquist, 1979; Melamed and Reuter, 1993; Stewart et al, 1999; Tan et al, 2008; Hubosky et al, 2013). The typically low-grade nature of the tumors and the frequent renal insufficiency seen in Balkan nephropathy underscore the importance of conservative treatment when possible. The degree of scarring of renal papillae seen in phenacetin abuse correlates in a dose-dependent manner with the risk of high tumor grade and progression. Calcification of renal papillae after analgesic abuse is associated with development of squamous carcinoma of the renal pelvis (Stewart et al, 1999).

There is a strong correlation of grade and stage for upper tract tumors. The single most important determinant of outcome is pathologic tumor stage (Tables 58-2 and 58-3) (Bloom et al, 1970;

Grabstald et al, 1971; Batata et al, 1975; Wagle et al, 1975; Babaian and Johnson, 1980; Cummings, 1980; McCarron et al, 1983; Huben et al, 1988; Anderstrom et al, 1989; Guinan et al, 1992b; Terrell et al, 1995; Messing and Catalona, 1998).

Upper tract tumors spread in the same ways as bladder tumors do, through lymphatic and hematogenous routes and by direct extension into contiguous structures, and most metastatic recurrences develop in the first 2 to 3 years after surgery (Brown et al, 2006). The common metastatic sites are the lungs, liver, bones, and regional lymph nodes. Preoperative evaluation for the extent of disease includes chest radiography, abdominal CT, liver function tests, and occasional bone scintigraphy. The thin muscle layer of the renal pelvis and ureter may allow earlier penetration of invasive upper tract tumors than is seen in bladder neoplasms (Cummings, 1980; Richie, 1988). The renal parenchyma may be a barrier, slowing distant spread of stage T3 renal pelvis tumors. In contrast, periureteral tumor extension carries a high risk of early tumor dissemination along the periureteral vascular and lymphatic supply. Improved survival of patients with stage T3 renal pelvis tumors versus ureteral tumors has been reported by several investigators (Batata and Grabstald, 1976; Guinan et al, 1992a; Park et al, 2004). Guinan and colleagues (1992a) confirmed this observation among 611 patients treated at 97 hospitals and in a collection of 250 cases reported in the literature. The 5-year survival rates for patients with stage T3 tumors of the renal pelvis and ureter were 54% and 24%, respectively. In a multivariate analysis, patients with ureteral tumors had a higher local and distant failure rate than did those with renal pelvis tumors of the same stage and grade (Park et al, 2004). Some have proposed subclassification of renal pelvis tumors into pT3a for infiltration of the renal parenchyma and pT3b for invasion of peripelvic adipose tissue, because the patients with pT3b have an increased risk of recurrence (Rosigno et al, 2012). Renal pelvis and upper ureteral tumors spread initially from hilar to para-aortic and paracaval nodes, whereas distal ureteral tumors spread to pelvic nodes (Batata et al, 1975; Heney et al, 1981; Nocks et al, 1982; Mahadevia et al, 1983; McCarron et al, 1983; Jitsukawa et al, 1985; Geiger et al, 1986).

Prognostic Factors

Stage

Stage is currently the most important predictor of survival in patients with upper tract urothelial tumors (Png et al, 2008). The most commonly used staging system is the TNM system (see the section on staging). Prognosis decreases as stage increases; the most significant decrease in survival is observed in T3 tumors that have penetrated into the perirenal, renal sinus, or periureteral

fat (Grabstald et al, 1971). Extranodal extension in patients with nodal involvement appears to predict clinical outcomes (Fajkovic et al, 2012).

Grade

The traditional grading system used for bladder cancer is also applicable to upper urinary tract tumors. Broder's original system, modified by Ash, grades tumors from grade 1 to grade 4: Grade 1 tumors are primarily papillomas, and grade 4 tumors are highly anaplastic and poorly differentiated tumors (Melamed and Reuter, 1993). The World Health Organization's system, proposed by Mostofi, eliminates papillomas and grades tumors from grade 1 to grade 3. Tumor grading has also been divided into low grade and high grade (Epstein et al, 1998). Papillomas and papillary urothelial neoplasms of low malignant potential are also described. Certainly, tumors of high grade are more likely to invade into the underlying connective tissue, muscle, and surrounding tissues. Tumors of high grade are also more likely to be associated with concomitant CIS.

Location

There remains disagreement as to whether the location of an upper tract tumor affects prognosis. Some have argued that when renal pelvic and ureteral tumors are matched for stage, there is no significant difference in prognosis (Hall et al, 1998b; Isbarn et al, 2009). Other studies have suggested that renal pelvic tumors have a better prognosis than ureteral cancers, even when adjusted for stage (Park et al, 2004; Ouzzane et al, 2011a). Multifocality portends worse prognosis (Chromecki et al, 2012).

Tumor Architecture

Papillary tumors seem to have better outcomes than sessile lesions (Remzi et al, 2009; Fritsche et al, 2012). As in bladder cancer, CIS of the upper tract is associated with higher risk for disease progression and a likelihood of future development of invasive urothelial cancers. CIS of the distal ureter is most common in patients with bladder CIS treated with BCG (30% likelihood).

Hydronephrosis

The presence of hydronephrosis has been shown in various studies to be a valuable and independent predictive factor for advanced disease stage and survival in UTUC patients (Cho et al, 2007; Brien et al, 2010; Ito et al, 2011; Ng et al, 2011).

Tumor Size

Although the role of tumor size is still an evolving criterion, recent studies suggest that tumors greater than 3 to 4 cm may be associated with worse survival as well as a higher risk of bladder recurrence (Cho et al, 2007; Simone et al, 2009a).

Age

Advanced age is a predictor of recurrence-free, disease-specific, and overall survival (Shariat et al, 2010; Chromecki et al, 2011). It is unclear whether the tumor biology or difference in care of elderly patients is responsible for this observation. In the study by Chromecki and colleagues (2011), addition of Eastern Cooperative Oncology Group (ECOG) performance status to the multivariate analysis abolished this association. Nevertheless, most advanced-age patients are cured with radical surgery, so age alone should not preclude the standard of care treatment for this population.

Race

Review of SEER data showed that black non-Hispanic race is associated with increased mortality compared with white non-Hispanic

race (Raman et al, 2011). Comparison of Japanese and European patients revealed no differences in survival (Matsumoto et al, 2011).

Tumor Multifocality

Presence of tumor in two or more sites within urothelium is defined as multifocality and serves as an independent predictor of poor clinical outcome. In a study by Novara and colleagues (2007), presence of multifocality increased disease-specific mortality by a factor of 3. In another cohort of patients, presence of multifocality was associated with disease-specific survival on univariate but not on multivariate analysis (Brown et al, 2006).

Tumor Necrosis

Extensive necrosis has been shown to correlate with aggressive clinicopathologic features, including stage, grade, LVI, presence of CIS, sessile architecture, and lymph node metastases (Zigeuner et al, 2010). Presence of tumor necrosis was also reported to independently predict recurrence-free and cancer-specific survival (Simone et al, 2009a; Zigeuner et al, 2010). However, a recent multicenter study contradicted this observation; the presence of necrosis alone was not predictive of survival on multivariate analysis (Seitz et al, 2010). Further studies validating this feature are needed.

Lymph Node Involvement

Involvement of regional lymph nodes in UTUC is an independent factor predicting poor survival (Hall et al, 1998a; Brown et al, 2006; Margulis et al, 2009). Depending on the stage and grade of the tumor, up to 40% of patients appear to harbor lymphatic metastases. The current paradigms are shifting toward primary treatment with platinum-based neoadjuvant chemotherapy in the population with radiographic suspicion for lymph node involvement, with surgical consolidation offered only if a significant response is seen. Similarly to bladder carcinoma, lymph node density is an emerging factor for clinical prediction in UTUC. In a study of patients who underwent lymphadenectomy at the time of radical nephrectomy, lymph node density of 30% or more was associated with poor clinical outcomes (Bolenz et al, 2009).

Lymphovascular Invasion

LVI has been suggested to be an independent prognostic factor for disease-specific survival in UTUC and should be commented on in pathologic evaluation. Unfortunately, it is not seen on ureteroscopic biopsy specimens and serves only as a prognostic tool after surgical resection. In three single-center and two multicenter series including a total of 1841 patients with upper tract tumors, the prevalence of LVI varied from 23.7% to 37.8%. LVI correlated with increasing tumor stage and grade and with disease recurrence and disease-specific survival (Akao et al, 2008; Bolenz et al, 2008; Lin et al, 2008; Chung et al, 2009). Kikuchi and colleagues (2009) reported on a large international, 13-center collaborative series of 1453 patients who underwent radical nephroureterectomy for upper tract urothelial tumors. The overall prevalence of LVI was 24%. LVI correlated with tumor grade stage, lymph node status, and tumor necrosis. In multivariate analysis, LVI was an independent predictor of disease recurrence and survival for patients with either negative lymph nodes or unknown nodal status. However, LVI was not an independent predictor of outcome for patients with positive lymph nodes.

Molecular Biology (Chromosome Abnormalities) and Markers

The characterization of genetic pathways leading to UTUC is a work in progress. Despite similarities in the molecular basis of UTUC to bladder carcinoma, disparities on a genetic and epigenetic level make them divergent entities. Microsatellite instability and hypermethylation seem to emerge as key differences between upper and lower tract urothelial neoplasms. On the other hand, several gene

foci on chromosome 9 are mutated in 50% of the UTUC cases, and results of comparative genomic hybridization have shown concordance between tumors of renal pelvis and bladder in the losses at 2q, 8p, 9q, 11p, 13q, 17p, and 18q, and gains at 1q, 6p, 8q, and 17q chromosomes (Rigola et al, 2001). A more recent study by Zhang and colleagues (2010) found similar gene expression profiles in renal pelvic and bladder tumors, including common cytogenetic alterations +1p36, +6p22, +7, +8q22, -9p21, +11q, -13q, +17, +19q13, and +20q.

Despite multiple recent advances in the identification of molecular markers, none of them have been validated for clinical use. Future prospective studies may help provide insight into their utility as clinical prediction tools. Nevertheless, it is worth mentioning some of the markers that show promise as candidates for future development.

Cell Cycle Markers. The TP53 nuclear protein staining of cytology specimens obtained ureteroscopically appears to correlate well with the presence of UTUC. In one study, of 36 TP53-positive specimens 28 had simultaneous evidence of urothelial carcinoma; 80% of the remaining patients who were evaluated serially also had confirmed UTUC. All 14 TP53-negative studies occurred in patients with no sign of concurrent malignant disease on ureteroscopy (Keeley et al, 1997b). Zigeuner and associates (2004) reported that decreased TP53 immunoreactivity and TP53 overexpression in upper tract tumors were associated with advanced tumor stage and poor prognosis. However, the findings were not independent of stage and grade in multivariate analysis.

CDKN1B. CDKN1B (formerly p27), a cyclin-dependent kinase inhibitor, has been shown to predict the prognosis of upper tract tumors. In one study, low levels of CDKN1B staining were indicative of a worse disease-specific survival (Kamai et al, 2000).

Apoptosis. Expression of Bcl-2 and survivin correlates with advanced cancers, and levels of survivin are associated with disease-specific survival (Jeong et al, 2009).

Cell Migration and Invasion. Expression of E-cadherin and metalloproteinases (MMPs) are associated with poor prognosis. Immunohistochemistry of MMPs correlates with pT stage and disease-specific survival.

Angiogenesis. Hypoxia-inducible factor-1 α (HIF-1 α) is a transcription factor that plays an important role in cellular hypoxia adaptation. In a series of patients with upper tract UTUC, positive HIF-1 α expression was found in two thirds of patients (and was absent in normal urothelium). HIF-1 α was significantly associated with high T stage, nodal stage, and grade as well as cancer-specific survival (hazard ratio 2.23; $P = .004$) (Ke et al, 2008).

Cell Proliferation. Overexpression of Ki-67 predicts progression and disease-specific survival (Jeon et al, 2010) and development of metachronous tumors (Joung et al, 2008). Epidermal growth factor receptor (EGFR) is associated with stage, grade, and squamous differentiation of UTUC. Overexpression and immunoreactivity of nuclear factor- κ B (NF- κ B) are predictors of disease-specific survival and overall survival. HER2 overexpression, although rare in UTUC, correlates with higher stage and grade, but not survival.

Cell Differentiation. Uroplakin III expression is associated with lower stage and grade and disease-specific survival. On multivariate analysis it outperformed stage and lymph node status as a predictor of survival (Ohtsuka et al, 2006). Snail is associated with stage, grade, and LVI and is predictive of recurrence and disease-specific survival (Kosaka et al, 2010). In situ hybridization of telomerase mRNA component hTR is increased with advanced stage and may be associated with disease-free and overall survival (Nakanishi et al, 1999).

Mitosis. Aurora-A regulates spindle assembly during mitosis. Its overexpression is associated with presence of vascular invasion and recurrence (Scarpini et al, 2012).

MET and RON. Recently the roles of c-MET and RON, members of the MET proto-oncogene family of tyrosine kinases, have been studied in upper urinary tract tumors (Comperat et al, 2008). c-MET overexpression correlated with vascular invasion and a worse clinical outcome, whereas overexpression of RON did not correlate with outcome.

COX-2. Abnormal expression of cyclooxygenase-2 (COX-2) has been reported in many forms of human cancer, including bladder urothelial cancer. Kang and coworkers (2008) reported that abnormal expression of COX-2 in stromal cells of upper urinary tract cancers correlated with high tumor stage and grade and poor prognosis.

Microsatellite Instability. Patients with HNPCC, or Lynch syndrome, show genomic alterations in DNA mismatch repair genes (Amira et al, 2003). Furthermore, an inverted growth pattern of cancer has also been associated with microsatellite instability, with a sensitivity and specificity of 0.82 in one study. This finding suggests that microsatellite instability may serve as a marker for inverted growth in upper urinary tract cancers (Hartmann et al, 2003). Ho and coworkers (2008) have reported that a urine-based assay testing for a total panel of 77 markers for microsatellite instability in 30 patients detected 83.3% of cases of an upper urinary tract tumor. Testing for microsatellite instability on resected tumor and normal tissues to screen for Lynch syndrome is a well-established tool for colon cancer and could be considered particularly for those patients with UTUC meeting criteria suggestive of Lynch syndrome (Audenet et al, 2012).

Ploidy-Flow Cytometry. Tumor ploidy has been shown to correlate with survival in upper tract tumors. In one study, tumor aneuploidy was associated with poor 5- and 10-year survival rates of 25% and 0%, respectively (Blute et al, 1988).

Other Markers. Rapid urine tests for urothelial malignant neoplasms have been studied extensively for the purpose of identifying lower urinary tract tumors. Less is known about their value in upper tract cancers. Urinary levels of NMP22, a nuclear matrix protein-based marker, have been found to be elevated in patients with upper tract cancer (Carpinito et al, 1996). Although the sensitivity of this test for determining the presence of low-grade tumors is probably higher than that of cytology, the specificity is low. Urine FISH was reported to have a sensitivity of 87.5% and a specificity of 80% for detection of upper tract tumors in a small series (Akkad et al, 2007).

In one series, an analysis of fibrinogen-fibrin degradation products (AuraTek FDP) was compared with the bladder tumor antigen (BTA) test and urine cytology. In this study, the accuracy of the FDP test was 83% compared with 62% for BTA and 59% for cytology (Siemens et al, 2003). Telomerase activity has been shown to be present in most (>95%) upper tract UTUCs. It can be detected in exfoliated urinary specimens in a high percentage of patients and thus may prove to be a potentially useful marker (in addition to conventional cytology) to identify upper tract cancers (Wu et al, 2000).

Clinical Prediction Tools

Because clinical staging is difficult owing to the challenges in determining invasion on biopsy or imaging, and as the popularity of neoadjuvant approaches increases, clinical prediction tools have been developed to provide better risk stratification before definitive therapy, as well as after nephroureterectomy.

Preoperative. Various studies used clinical, radiographic, and pathologic factors to better determine the risk of invasive disease. The largest analysis of a multi-institutional patient cohort by Margulis and colleagues (2010) showed that combination of grade, tumor architecture, and location achieved 76.6% accuracy as a prognostic tool in predicting non-organ-confined disease.

Postoperative. Construction of nomograms to predict oncologic outcomes after nephroureterectomy using demographic and clinicopathologic data has attracted much interest in the past few years. Using SEER data, Jeldres and colleagues (2010b) looked at patient age, race, and sex; tumor grade, stage, and location; nodal status; and bladder cuff removal status at surgery. The nomogram with the greatest predictive value for 5-year cancer-specific mortality-free rate (75.4%) included patient age, tumor grade, pT stage, and nodal involvement. Yates and colleagues (2012) pooled data from 21 French institutions to develop a nomogram for 5-year cancer-specific survival. On multivariate analysis, T stage, N status, grade, age, and location were associated with cancer-specific survival, and

the resulting nomogram had an accuracy of 78%. In another study, pathologic characteristics of an international cohort of patients (Cha et al, 2012) were used to build predictive tools for recurrence and disease-specific survival. On multivariate analysis, T stage, presence of nodal disease, LVI, sessile architecture, and presence of CIS were associated with recurrence-free survival. For cancer-specific survival, T stage, lymph node metastasis, LVI, and sessile tumor architecture showed independent prognostic value. These nomograms predicted recurrence-free and cancer-specific survival with 76.8% and 81.5% accuracy, respectively. In a more recent study (Roupret et al, 2013), the data from French and international cohorts of patients were merged to develop an optimized nomogram for cancer-specific survival. This nomogram combined patient age, T stage, N stage, tumor architecture, and LVI with an ensuing discriminative accuracy of 0.8.

To predict intravesical recurrence after nephroureterectomy with bladder cuff excision, data from multiple European and North American centers was analyzed (Xylinas et al, 2013). Bladder recurrence at 3, 6, 12, 18, 24, and 36 months was predicted with 67.8% accuracy using the reduced-type nomogram, which was based on patient age, gender, prior bladder cancer, tumor location, stage, presence of CIS, and lymph node involvement. When surgical characteristics (laparoscopic vs. open surgery and type of distal ureter management) were added to this model, accuracy of the nomogram increased to 69%. The authors suggested using this nomogram for use of postoperative intravesical instillation of chemotherapy and optimization of cystoscopic surveillance schedule.

TREATMENT

Surgical Management

The treatment of upper tract urothelial tumors has undergone significant changes. The relatively low frequency of these lesions and the existence of only three prospective randomized trials do not permit absolute conclusions about treatment impact on outcomes. In the past, treatment recommendations were based, at least in part, on practical limitations in follow-up and detection of local disease recurrence. Technologic improvements in imaging and, most important, direct endoscopic visualization of all levels of the urinary tract allow earlier and more accurate initial diagnosis and treatment and improved follow-up. Treatment may be based primarily on the risk the tumor poses and on the efficacy of a specific treatment rather than on other considerations. The specific indications and techniques for each form of treatment (open vs. laparoscopic radical nephroureterectomy; open vs. retrograde endoscopic vs. percutaneous renal-sparing tumor ablation) are addressed later in this chapter. However, the following introductory considerations apply.

The least invasive treatment necessary for safe control of the tumor is preferred, but never at the risk of compromising oncologic control, as UTUC is unforgiving to surgical indiscretions, which also are rarely able to be salvaged by other modalities. Most upper tract urothelial tumors are not large or bulky. Thus, laparoscopic surgery is ideal, at least for the renal portion of radical nephroureterectomy when the tumor warrants removal of the entire renal unit. A variety of approaches with various combinations of laparoscopic and open techniques are used for distal ureterectomy. Select low-grade non-invasive upper tract tumors can be managed initially by ablative renal-sparing surgery. Retrograde ureteroscopy and ureteropyeloscopy are preferred when tumor size, number, and access allow complete tumor ablation. Percutaneous antegrade tumor ablation is chosen when the anatomy and the tumor do not allow complete ablation through a retrograde approach.

Radical Nephroureterectomy

Indications. Radical nephroureterectomy with excision of a bladder cuff is the gold standard for large, high-grade, suspected invasive tumors of the renal pelvis and proximal ureter (Batata and Grabstald, 1976; Skinner, 1978; Babaian and Johnson, 1980; Cummings, 1980; Murphy et al, 1981; Nocks et al, 1982; McCarron

et al, 1983; Richie, 1988; Williams, 1991; Messing and Catalona, 1998). Radical surgery also retains a role in treatment of low-grade, noninvasive tumors of the renal pelvis and upper ureter when they are large, multifocal, or rapidly recurring despite maximal efforts at conservative surgery.

Techniques

Open Radical Nephroureterectomy. There are a variety of surgical approaches to open radical nephroureterectomy, which are mostly dictated by the surgeon's experience and patient's body habitus. Nephroureterectomy is one of the few multi-quadrant operations that urologists perform; a variety of approaches are attempted. Patient may be positioned supine or in modified flank position. In male patients the genitalia are included in the surgical field so that the bladder catheter may be accessed during the procedure. Our preference is a midline approach, which gives the most optimal exposure to the retroperitoneal lymph nodes and bladder. This incision, however, may be limiting in exposure of the upper pole of the left kidney, especially in obese patients. Other incisions are flank, subcostal, and thoracoabdominal. The choice of these incisions necessitates using an additional Gibson, midline, or Pfannenstiel incision for bladder cuff removal (Fig. 58-6).

After incision of the white line of Toldt, the ipsilateral colon is mobilized to expose the Gerota fascia. Ideally, the hilum is controlled before excessive manipulation of the kidney and ureter. The renal hilum is exposed, reflecting duodenum medially on the right side. For left-sided tumors, care should be taken to avoid injury to the pancreatic tail and spleen. The renal artery and vein are secured and divided in a standard manner. Various options for ligating the vessels are used, including suture ligature, ties, a combination of ties with clips, and stapling devices using an endovascular load. The ureter is typically ligated at this time to prevent migration of tumor fragments into the bladder. The entire kidney is mobilized, taking care to stay outside of the Gerota fascia (Fig. 58-7). On the right side, attachments between the liver and kidney, and on the left side the splenorenal ligament, are incised, allowing mobility of the kidney. Traditionally, the ipsilateral adrenal gland has been removed

with the specimen, although adrenalectomy does not aid the oncologic control of UTUC, unless its direct involvement is suspected based on preoperative imaging or intraoperative examination. Thus as a routine, concomitant adrenalectomy is unnecessary.

Management of Distal Ureter and Bladder Cuff

Complete removal of the distal ureter and bladder cuff offer superior oncologic outcomes to incomplete resection. In addition, adequate cystoscopic surveillance of a residual distal ureter stump after nephroureterectomy is virtually impossible, contributing to high rates of local recurrence. **Therefore the entire distal ureter, including the intramural portion and the ureteral orifice, has to be removed.** The kidney and proximal ureter may be kept in continuity with the distal segment; however, the bulk of the attached kidney

Figure 58-6. Choice of incision for radical nephroureterectomy (midline, subcostal, flank or thoracoabdominal) is dictated by surgeon's preference and experience. Unless a midline incision is used, an additional Gibson, low midline, or Pfannenstiel incision is necessary for bladder cuff removal.

Figure 58-7. A, Radical nephroureterectomy specimen including kidney, Gerota fascia, and ureter. The adrenal gland should not be routinely removed with the specimen, unless its involvement is suspected. B, This bivalved specimen shows a normal collecting system and renal pelvis without tumor. (Courtesy Donna Hansel, MD, PhD, Department of Pathology, University of California, San Diego.)

makes its manipulation difficult, and apart from helping the pathologist with specimen orientation, this technique is not necessary as long as the distal ureter is divided in a controlled manner between ties or clips at a location that is free of gross tumor. There are at least five different techniques described for distal ureterectomy, and most of these apply to both open and laparoscopic surgery.

Traditional Open Distal Ureterectomy. With a Gibson, low midline, or Pfannenstiel incision, bladder cuff removal is performed using a transvesical (Fig. 58-8), extravesical (Fig. 58-9), or combined approach. Any of these methods is acceptable, provided that the whole ureter, including the intramural portion and mucosa of the ureteral orifice, are removed with the surgeon's visual confirmation

Figure 58-8. Complete distal ureterectomy with bladder cuff is performed by combined extravesical and transvesical dissection.

Figure 58-9. Complete distal ureterectomy by extravesical approach. Traction is placed, everting the orifice outside the bladder. Care must be taken to ensure complete removal and to avoid injury to the contralateral ureteral orifice.

of complete resection. For the extravesical approach, distal ureter is freed toward the bladder to the point of intramural ureter. Gentle traction on the ureter and full bladder may aid in this step; however, for adequate access to the entire intramural ureter, the lateral pedicle of the bladder (obliterated artery; superior, middle, and inferior vesical arteries) must be ligated and divided. Care must be taken to avoid uncontrolled entry to the urinary tract. A cuff of bladder is removed en bloc with ureter by applying a clamp to bladder wall and excising the full intramural portion of the ureter, taking care to stay away from the contralateral ureteral orifice. In the transvesical approach, an anterior cystotomy is made and intravesical dissection of the ureter is performed, including a traditional 1 cm mucosal area around the orifice. A wider margin can be taken if a gross tumor is seen protruding from the orifice; and if invasive intramural tumor is suspected, an en bloc partial cystectomy may be required to ensure negative margins. Cystotomy defects are closed in two layers with interrupted or running absorbable sutures: The first layer should incorporate mucosa, and the second layer should include detrusor muscle and adventitia. A Foley catheter is placed and maintained for 5 to 7 days, and a suction drain is left in the perivesical space.

Transvesical Ligation and Detachment Technique. The transvesical ligation and detachment technique mimics open bladder cuff removal. Before the nephrectomy portion, the patient is placed in the low lithotomy position, a cystoscope is passed into the bladder and kept in place, and the bladder is filled. One or two 5-mm trocars are placed intravesically from the suprapubic area. An Endoloop is placed around the ureteral orifice, and a ureteral catheter is advanced into the ureter through the Endoloop. With a Collins knife the bladder cuff is incised, and this incision is carried into the extravesical space (Fig. 58-10). Retraction is provided by the grasper through one of the trocars. Once the ureter is freed, the Endoloop is cinched around the ureter as the catheter is removed. This creates a "closed" urothelium with subsequent en bloc removal of specimen, and extravasation of fluid from the bladder is minimized by continuous suction from the second intravesical trocar. There has been excellent clinical success reported with this technique (Gill et al, 1999), but the learning curve is difficult, and repositioning of the patient for the nephrectomy portion is required. Patients with distal ureteral tumors, disease in the bladder, or prior pelvic radiation are not candidates for this technique.

Transurethral Resection of the Ureteral Orifice. Transurethral resection of the ureteral orifice is also referred to as a "pluck" technique and can be used in patients with proximal tumors and absence of bladder disease (Abercrombie et al, 1988; Palou et al, 1995). With the patient in the lithotomy position, the resectoscope is inserted into the bladder and aggressive resection of the ureteral orifice and intramural ureter is performed down to the perivesical fat (Fig. 58-11). This facilitates the plucking of the distal ureter during the nephrectomy portion of the procedure. Even though equivalent oncologic outcomes have been reported in limited studies (Walton et al, 2009), concerns about tumor seeding of the extravesical space and the potential for leaving incompletely resected ureter have caused this technique to be largely abandoned (Jones and Moisey, 1993; Arango et al, 1997).

Intussusception (Stripping) Technique. The intussusception technique was initially described in 1953, and several modifications have been described since then (McDonald, 1953; Clayman et al, 1983; Roth et al, 1996; Angulo et al, 1998). It is contraindicated in the presence of ureteral tumors. At the beginning of the procedure, a ureteral catheter is placed in the ureter, and nephrectomy is carried out as usual. The distal ureter is isolated extravesically, and a tie is placed around it, securing the catheter to the ureter (Fig. 58-12). After the nephrectomy portion has been completed, the ureter is transected between ties and the bladder cuff is incised cystoscopically with a Collins knife. By pulling on the ureteral catheter, the distal ureter is everted inside the bladder. The intussuscepted ureter is then removed by traction out of the urethra. The edges of the bladder mucosa can be fulgurated. The concerns with this technique include exposure of bladder urothelium to ureteral mucosa with extensive manipulation of the ureter and the potential for

Figure 58-10. A ureteral catheter is placed, and two laparoscopic ports are placed transvesically. The ureteral orifice is tented up; a loop is placed around the orifice to occlude the opening and to place traction on the ureter. A Collins knife then facilitates the dissection to the extra-vesical space.

incomplete intramural ureter excision. In addition, a failure rate of 18.7% has been described in which there was disruption of the ureter during manipulation and the need for an additional surgical incision (Giovansili et al, 2004).

Total Laparoscopic Technique. A total laparoscopic approach is attractive to many because it avoids incision into the urinary tract, and in experienced hands the operative time is reduced. Initially, cystoscopy is performed and the ureteral orifice is cauterized, which may be preceded by placement of a ureteral catheter and incision of an intramural tunnel at the 12 o'clock position. The nephrectomy portion is performed as usual, and the distal ureter is traced to detrusor muscle. The ureteral dissection is carried down to the bladder. The detrusor muscle is split and the ureter retracted in antegrade direction. The endovascular stapler is then used to place a staple line as distally as possible. A fulguration mark helps serve as an identifier of the bladder cuff (Fig. 58-13). The concerns with this technique include the potential for leaving ureter mucosa within the staple line and the inability of the pathologist to evaluate the distal margin because of the presence of staples. Laparoscopic stapling has been associated with a higher risk of positive margins, which in this disease is associated with significantly reduced survival (Steinberg and Matin, 2004; Matin and Gill, 2005). Contraindications include the presence of distal ureteral tumors.

Adjuvant Therapy Following Distal Ureterectomy to Decrease Bladder Recurrence. Bladder tumor recurrence after nephroureterectomy is a relatively common event. Although some cases are from the field effect (Hafner et al, 2002), most researchers believe that most instances are a result of the monoclonal theory of tumor seeding, especially with downstream recurrences (Takahashi et al, 2001; Catto et al, 2006). This is also supported by the patterns of recurrence after surgical treatment, occurring more frequently at the surgical site of distal ureterectomy. In an effort to decrease this

recurrence rate, several authors have described a single postoperative dose of intravesical mitomycin. O'Brien and colleagues (2011) described a single postoperative dose of mitomycin C in a randomized prospective nonblind trial. They found that a single postoperative dose of mitomycin C was able to reduce the risk of bladder tumor within the first year after nephroureterectomy to 11% from over 50%. Another randomized prospective study by Ito and colleagues (2013) using pirarubicin showed very similar findings. Use of mitomycin after transurethral resection of bladder tumor (TURBT) had already shown efficacy in a study. This is an evolving area but should be considered as part of the treatment program after any treatment of the upper tracts in an effort to decrease the risk of bladder seeding, particularly because both studies showed very high tolerability and a low incidence of adverse events.

Lymphadenectomy

The role and extent of lymphadenectomy for UTUC has been under debate for a long time (Nakazono and Muraki, 1993; Komatsu et al, 1997). Limited or regional lymphadenectomy is included with radical nephroureterectomy. For renal pelvis and proximal or middle ureteral tumors, this includes the ipsilateral renal hilar nodes and the adjacent para-aortic or paracaval nodes, and pelvic nodes for distal ureteral tumors (Grabstald et al, 1971; Batata et al, 1975; Batata and Grabstald, 1976; Skinner, 1978; Johansson and Wahlquist, 1979; Babaian and Johnson, 1980; Cummings, 1980; Heney et al, 1981; McCarron et al, 1983; Richie, 1988; Williams, 1991; Messing and Catalona, 1998; Brausi et al, 2007; Kondo et al, 2007; Abe et al, 2008). This dissection adds little time or morbidity to the surgery. Kondo and Tanabe (2012) proposed an extended lymphadenectomy template based on the location of the tumor (Fig. 58-14). For tumors of the renal pelvis this includes ipsilateral

Figure 58-11. The entire orifice and intramural ureter are resected transurethrally until the extravascular fat is seen. This portion is usually done at the beginning but can be done at the end of the procedure.

Figure 58-12. With the intussusception technique, a ureteral catheter is placed at the beginning of the case. After nephrectomy the ureter is divided and the catheter is secured to the distal portion of the ureter. The patient is moved to the lithotomy position, and the ureter is intussuscepted into the bladder with retrograde traction. A resectoscope is used to excise the attached orifice.

Figure 58-13. The ureter is dissected extravesically to the ureteral orifice. Lateral traction is placed on the ureter, everting the orifice, and the endovascular stapling device is placed at the distal margin, providing simultaneous ligation and division of the distal ureter at the level of the bladder. A cystoscope can be placed to ensure that the entire ureter is removed.

Figure 58-14. A, In addition to ipsilateral hilar nodes, the extended lymphadenectomy template for tumors of the renal pelvis includes paracaval, retrocaval, and interaortocaval lymph nodes for right-sided, and para-aortic lymph nodes for left-sided tumors. The inferior mesenteric artery marks the inferior boundary of the template. B, For tumors of the upper two thirds of the ureter, this template is extended to the level of bifurcation of aorta. C, The extended lymphadenectomy template for tumors in the distal ureter includes ipsilateral common, external and internal iliac, obturator, and presacral nodes.

hilar, paracaval, retrocaval, and interaortocaval nodes up to the level of the inferior mesenteric artery for right-sided tumors, and ipsilateral hilar and para-aortic nodes up to the level of the inferior mesenteric artery for left-sided tumors. For tumors of the upper two thirds of the ureter (above the crossing of the inferior mesenteric artery with the common iliac artery), the template is similar, but the distal border of dissection is extended to the level of aortic bifurcation. For tumors of the lower third of the ureter, these include ipsilateral obturator, internal, external, and common iliac, and presacral packets.

The analysis of the literature is complicated by lack of uniformity in templates for lymphadenectomy and the inconsistent pattern of spread compared with bladder cancers. Lymph node involvement is reported in 12% to 25% of patients with UTUC, although it increases with advanced stage and grade. The reported numbers are 0% to 3% in pTa/pTis, 0% to 6.3% in pT1, 0% to 40% in pT2, 19% to 47% in pT3, and 20% to 100% in pT4. However, the median number of lymph nodes removed and the boundaries of lymphadenectomy varied widely in these studies (Weight and Gettman, 2011). Multiple series of lymphadenectomy at the time of nephroureterectomy (Secin et al, 2007; Roscigno et al, 2008, 2009; Abe et al, 2010; Lughezzani et al, 2010a; Burger et al, 2011) confirm that oncologic outcomes for patients with pN0 are better than pNx, and worse for pN+ compared with pNx groups. The importance of number of lymph nodes removed was addressed by Roscigno and colleagues (2009), who reported that removal of eight or more nodes increased the chance of finding positive lymph nodes by 49% and improved disease-specific survival for those with pT1 or greater disease. Kondo and colleagues (2010) stressed the importance of the dissection template over the nodal counts for survival difference. Several other studies explored the effects of lymphadenectomy on survival. Brausi and colleagues (2007) reported increased overall survival for T2 to T4 patients who underwent lymphadenectomy versus those who had nephroureterectomy only, suggesting a potential therapeutic benefit. Kondo and colleagues (2007) observed a survival advantage when complete lymphadenectomy was performed in patients with pT3 or higher disease. In both of those studies, univariate analysis was performed, which may not have adjusted for presence of confounding variables.

In summary, prospective studies are needed to assess the role of lymphadenectomy in UTUC. As with bladder cancer, it appears to have prognostic and therapeutic value in patients with invasive disease (T2 to T4), and extended lymphadenectomy is beneficial for accurate staging.

Results. Multiple series reported on strong correlation of outcome with tumor stage and grade. Recently, additional prognostic factors, such as tumor architecture, presence of CIS, LVI, and lymph node positivity, were shown to correlate to oncologic outcomes (Margulis et al, 2009; Cha et al, 2012).

Complete ureterectomy with bowel cuff excision should accompany nephroureterectomy for UTUC. The risk of tumor recurrence in a remaining ureteral stump is 30% to 75% (Bloom et al, 1970; Strong et al, 1976; Johansson and Wahlquist, 1979; Babaian and Johnson, 1980; Kakizoe et al, 1980; Mullen and Kovacs, 1980; McCarron et al, 1983). Techniques such as simple extravesical dissection and tenting up of the ureter will result in an incomplete removal of the distal ureter (Strong et al, 1976). Smith and colleagues (2009) presented data on a single-center experience comparing oncologic outcomes following variations in technique of the distal ureterectomy. The techniques were divided into definitive, which included any approach that resulted in excision of the distal ureter with bladder mucosal cuff, and nondefinitive, which included detachment of the ureter at or above the level of detrusor. Nondefinitive management of the distal ureter was associated with higher rates of local and distal recurrence and inferior disease-specific and overall survival. Complete ureterectomy with a bowel cuff should also be performed in the setting of a renal unit draining into a urinary diversion. Tumor recurrence rates up to 37.5% have been reported when ureteroenteric anastomosis was not removed (Mufti et al, 1988).

Researchers in multiple series have recommended radical nephroureterectomy as a treatment that provides optimal oncologic control (Batata et al, 1975; Johansson and Wahlquist, 1979; Murphy et al, 1980; McCarron et al, 1983; Zungri et al, 1990). Margulis and colleagues (2009) conducted a retrospective review of 1363 patients from 12 tertiary care centers worldwide who underwent radical nephroureterectomy with curative intent. Although the data for open and laparoscopic cases were pooled together, most

patients (77%) underwent open nephroureterectomy. The pT stage was evenly distributed among Ta, T1, T2, and T3, but less than 5% of patients had T0, Tcis, or T4 each. Two thirds of patients had high-grade tumors, and 28% had concomitant CIS. Around 10% of patients had lymph node positivity, and 16% received perioperative chemotherapy. Disease recurrence was observed in 28% of patients at a median of 10.4 months. During a median follow-up of 37.2 months, 30% of patients died, and 61% of the deaths were attributable to the patients' disease. In summary, radical nephroureterectomy provides reasonable oncologic control, with outcomes largely dependent on clinicopathologic characteristics. It is warranted for patients with high-grade invasive organ-confined or locally advanced disease (stage T1 to T4, N0 to N2, M0). **Comparative data of extirpative versus conservative management are lacking, because the populations of patients who undergo these surgeries are very different. Treatment decisions in patients with compromised renal function must balance the potential curative effect of radical surgery with the morbidity associated with dialysis.**

Laparoscopic Radical Nephroureterectomy

Indications. The indications for laparoscopic nephroureterectomy are the same as those for open nephroureterectomy. Exceptions may include large bulky tumors with involvement of adjacent structures or those wherein extended lymph node dissections may be considered. Laparoscopic nephroureterectomy can be performed by transperitoneal, retroperitoneal, hand-assisted (Ni et al, 2012), and robotic approaches. **In general, the laparoscopic approach shows a significant decrease in morbidity compared with an open surgical approach for appropriately selected patients.** All laparoscopic techniques involve two distinct portions of the procedure: nephrectomy and proximal ureterectomy, and excision of the distal ureter with intact specimen extraction for accurate staging. Management of the distal ureter is described previously in the chapter. One should bear in mind several factors with laparoscopic nephroureterectomy, including the risk of tumor seeding from both the ureter and the bladder. For these reasons, removal of an intact specimen is desirable. The incision should be strategically placed for both extraction of the specimen and dissection of the distal ureter. Because an incision is necessary regardless of the approach chosen, some techniques for avoidance of a second incision for the distal ureter described previously are less useful.

Technique

Transperitoneal Laparoscopic Nephroureterectomy

Laparoscopic Removal of Kidney Down to Mid-Ureter. The patient is placed supine with the ipsilateral hip and shoulder rotated approximately 20 degrees (Fig. 58-15). The patient is secured to the table and can be easily moved from the flank position (nephrec-

Figure 58-15. The patient is positioned on the table in a modified lateral decubitus position with the ipsilateral flank rotated up 15 degrees. The patient is secured to the table at the chest, waist, and lower extremity. This setup allows the patient to be moved to the full flank or supine position with simple rotation of the operating table. (From Jarrett TW. Laparoscopic nephroureterectomy. In: Bishoff JT, Kavoussi LR, editors. Atlas of laparoscopic retroperitoneal surgery. Philadelphia: Saunders; 2000. p. 105.)

tomy portion) to the modified supine position (open portion) by rotating the operative table. The ipsilateral flank and urethra are prepared and draped, and a Foley catheter is placed before insufflation of the abdomen.

The abdomen is insufflated, and three or four trocars are placed as outlined in Figure 58-16, with the first usually being the lateral trocar. Subsequent trocars are placed under direct vision. With this configuration, the camera is kept at the umbilicus for the entire procedure. The upper midline and lateral trocars are used by the surgeon for the dissection of the kidney and the proximal half of the ureter. The lower midline and lateral trocars are used for the dissection of the distal ureter. A 3-mm trocar just below the xiphoid can be helpful in retracting the spleen and liver for left- and right-sided lesions, respectively. The exception is with obese patients, in whom shifting of the trocars may be necessary to provide optimal visualization (Fig. 58-17). If a hand-assist approach is chosen, the hand port site should be placed so that it can be used for the dissection of the distal ureter and open bladder cuff as indicated.

The table is rotated so that the patient is in the flank position. The peritoneum is incised along the white line of Toldt from the level of the iliac vessels to the hepatic flexure on the right and to the splenic flexure on the left. The colon is moved medially by releasing the renocolic ligaments while leaving the lateral attachments of the Gerota fascia in place to prevent the kidney from

Figure 58-16. Port configuration for laparoscopic-assisted nephroureterectomy. Three ports are typically used for the kidney and upper ureteral dissection. A fourth midline port between the umbilicus and symphysis can be placed, if needed, for further ureteral dissection. The incision is then strategically placed to allow the distal ureteral dissection and specimen removal. The choice of incision largely depends on patient factors and level of dissection reached during the laparoscopic portion of the procedure. A low abdominal (midline or Pfannenstiel) incision is favored if the dissection is below the iliac vessels. A Gibson-type incision will give exposure of the more proximal ureter, if necessary.

Figure 58-17. For obese patients undergoing laparoscopic-assisted nephroureterectomy, the trocars are shifted laterally to accommodate the increased distance from the kidney.

Figure 58-18. The vessels of the renal hilum are carefully dissected, and the endovascular stapling device, with a vascular load, is used to simultaneously ligate and divide the vessels in a controlled environment. (From Jarrett TW. Laparoscopic nephroureterectomy. In: Bishoff JT, Kavoussi LR, editors. *Atlas of laparoscopic retroperitoneal surgery*. Philadelphia: Saunders; 2000. p. 112.)

“flopping” medially. The colon mesentery should be mobilized medial to the great vessels to facilitate dissection of the ureter, renal hilum, and local lymph nodes as needed.

Proximal Ureteronephrectomy. The proximal ureter is identified, just medial to the lower pole of the kidney, and dissected toward the renal pelvis, avoiding skeletonization and maintaining copious periureteral fat if any tumor is located in this area. If an invasive ureteral lesion is suspected, the dissection should include a wide margin of tissue. The renal hilum is identified, and its vessels are exposed with a combination of blunt and sharp dissection. The artery is ligated and divided by use of a stapling device with a vascular load or multiple clips. The renal vein is then divided in a similar fashion (Fig. 58-18). With vascular control ensured, most prefer to ligate the ureter with a clip as previously described, and the kidney is dissected free outside the Gerota fascia. Similar to the procedure described for open nephroureterectomy, the adrenal gland does not need to be removed routinely. The ureteral dissection is continued distally, keeping in mind that the ureteral blood supply is generally anteromedially located in the proximal third, medially located in the middle third, and laterally located in the distal third. Dissection of the lower half may require placement of the fourth trocar. In the area of primary disease, surrounding tissue should be left to provide an adequate tumor margin. The ureteral dissection is continued as far as is technically feasible. If the distal limits of the dissection are below the level of the iliac vessels, the remainder of the procedure can easily be completed through a lower abdominal incision. The specimen is placed in the pelvis, and the renal bed is inspected meticulously for bleeding. At this time, the 10-mm port sites are closed before proceeding to the open portion of the case.

Open Distal Ureterectomy with Excision of Bladder Cuff. The patient is now moved to the supine position, which can usually be done without reoperation, and a low midline Pfannenstiel or Gibson incision is made. The choice of incision largely depends on the tumor location, the body habitus of the patient, and the most caudal level of ureteral dissection attained during the laparoscopic portion. The Gibson incision is preferable when the distal ureter cannot be freed laparoscopically to the level of the iliac vessels.

Dissection of the Distal Ureter. If one is to consider a total laparoscopic procedure or to minimize the open distal portion, the ureteral dissection needs to continue to the level of the bladder. The patient is placed in the Trendelenburg position to move the bowel contents out of the pelvis. The peritoneal incision is extended from the level of the iliac vessels into the pelvis lateral to the bladder and medial to the median umbilical ligament (Fig. 58-19). The vas

Figure 58-19. The peritoneal incision is continued below the iliac vessels medial to the median umbilical ligament and lateral to the bladder. The vas deferens is divided between clips in the male patient. In the female patient the round ligament is divided, giving full exposure of the distal ureter to the bladder.

deferens in male patients and the round ligament in female patients is clipped and divided if exposure is limited. The ureter can now be traced between the bladder and the median umbilical ligament down to its origin at the bladder. Optimal exposure of the entire intramural ureter is gained by division of the lateral pedicle of the bladder, allowing medial rotation of the bladder exposing the entire length of ureter. The bladder cuff may be dissected extravesically, freeing the ureter from the surrounding detrusor muscle; alternatively, opening the bladder immediately around the ureteral orifice allows direct visual confirmation for complete resection of the bladder cuff. Yet another alternative during a complete extravesical approach is flexible cystoscopy in confirming complete ureterectomy and patency of the contralateral ureteral orifice. The techniques for open distal ureterectomy and bladder cuff excision are described in the section on open techniques.

Robotic-Assisted Laparoscopic Nephroureterectomy. With the increased use of robotics in urologic surgery, robotic-assisted nephroureterectomy has become a feasible alternative to more traditional open or laparoscopic technique. The availability of the da Vinci S system with longer instruments and improved range of motion with less arm clashing has allowed performing the surgery without the need to re-dock the robot or reposition the patient for the distal ureterectomy portion. Proper port positioning is paramount to the success of this technique (Fig. 58-20). The 12-mm camera port is placed at the level of umbilicus, lateral to rectus sheath, followed by placement of cephalad (port 1) and caudad (port 2) 8-mm robotic ports, both of which are positioned 7 to 8 cm away from the camera port on the same line. The third robotic port (port 3) is placed about 5 cm cranial to iliac crest, close to the anterior axillary line. The assistant port is placed in the midline in or around the umbilicus. Docking the robot, the left arm is placed in port 1, the right arm is placed in port 2, and the fourth arm is placed in port 3 and is used for retraction. Once the nephrectomy portion is completed, the retraction instrument is moved to port 1 and the left arm to port 3 for distal ureter and bladder cuff dissection. For extravesical dissection of the ureter, a distended bladder is helpful in tracing the ureterovesical junction. Once the distal

Figure 58-20. Port configuration for robot-assisted laparoscopic nephroureterectomy. For nephrectomy and upper ureterectomy portion, the retraction instrument is placed in port 3, and for distal ureterectomy with bladder cuff removal, the retraction instrument is moved to port 1 and the left arm to port 3.

ureter is dissected out of the detrusor, the bladder can be emptied. Placement of stay sutures medial and lateral to the incision site of the ureterovesical junction aids in subsequent reconstruction of the bladder. The bladder should be closed in two layers (Hemal et al, 2011).

Results. The first laparoscopic nephroureterectomy was performed in 1991 by Clayman and associates. Since that time the technical aspects and safety of laparoscopic procedures have been well established. There are multiple reviews and published series of laparoscopic nephroureterectomy with varying techniques (Jarrett et al, 2001; Stifleman et al, 2001; Bariol et al, 2004; Hsueh et al, 2004; Matin and Gill 2005; Wolf et al, 2005; Ni et al, 2012; Rai et al, 2012). Each varies with regard to approach (transperitoneal vs. retroperitoneal), management of the distal ureter by open removal, transurethral resection, and total laparoscopic management. As with other laparoscopic renal procedures, there is no clear-cut benefit of any one approach with regard to morbidity, cosmesis, or return to activity. All, however, show a benefit with regard to morbidity compared with open surgery. More recently, the robotic technique has been described (Hemal et al, 2011) with only short-term follow-up.

The efficacy of laparoscopic nephroureterectomy is being established for cancer control. With intermediate and long-term follow-up, cancer-related outcomes appear comparable to those of the open counterpart (McNeill et al, 2000). El Fettouh and colleagues (2002), in a multi-institutional study with 116 patients, showed the local and bladder recurrence rates to be 2% and 24%, respectively. The rate of distant metastasis was 9%, and positive margins were seen in 4.5% of cases. More recently, Berger and associates (2008) showed 5-year cancer-specific survival rates of 80%, 70%, 68%, 60%, and 0% for stage Ta/Tis, T1, T2, T3, and T4 lesions, respectively. Schatteman and associates (2007) similarly showed cancer-specific survival rates of 100%, 86%, 100%, 77%, and 0% for stage Ta, T1, Tis, T3, and T4 lesions. In both studies there was a worsening prognosis with increasing tumor stage. Long-term data are available from Muntener and associates (2007a), who studied 37 patients with follow-up of 60 to 148 months. In this study, 11 patients had disease progression and died 7 to 59 months after the operation. Tumor stage was the only factor significantly associated with disease recurrence. Ni and colleagues (2012) compared open with laparoscopic outcomes in a larger review of comparative studies. Although the results were not statistically significant, the study showed that laparoscopic surgery had a higher 5-year cancer-specific survival and lower bladder and overall recurrence rates compared with open techniques. With appropriate patient selection, the laparoscopic approach offers reliable safety and oncologic efficacy with the advantage of lower morbidity for well-selected patients. In the only surgical randomized controlled trial comparing laparoscopic and open extirpative surgery, Simone and colleagues (2009b) showed no difference in metastasis-free and cancer-specific survival

in patients with organ-confined disease. However, in this study, patients with high-grade disease or pT3 or higher stage benefited from open nephroureterectomy.

Local recurrence and port-site seeding are major concerns. There have been 12 reported instances of port-site seeding involving UTUC. Two of these cases were discovered after simple nephrectomy for presumed benign disease in which the principles of surgical oncology were inadvertently not followed (Ahmed et al, 1998; Otani et al, 1999). All were for high-grade disease. Muntener and associates (2007b) reported a single case of local recurrence among 166 cases. In this instance there was obvious violation of the ipsilateral urinary tract, noted perioperatively. Although the potential for seeding exists, it seems to be decreasing and the risk does not appear any higher than that for the open surgical counterpart as long as good surgical principles are followed.

In summary, there does not appear to be a significant difference between laparoscopic and open nephroureterectomy when the principles of surgical oncology are followed. Management of the bladder cuff still has shown variability and a tendency toward higher recurrences with minimally invasive approaches. Lymphadenectomy can be performed laparoscopically and should be used based on the clinical situation. Even extended lymph node dissections can be considered in those with advanced laparoscopic skills.

Open Nephron-Sparing Surgery for Renal Pelvis Tumors

Indications. Open conservative surgery may be considered in rare cases of renal pelvic tumors when nephron sparing for preservation of renal function is required (Gittes, 1966; Petkovic, 1972; Mazeman, 1976; Johnson and Babaian, 1979; Babaian and Johnson, 1980; Cummings, 1980; Wallace et al, 1981; Tomera et al, 1982; McCarron et al, 1983; Zincke and Neves, 1984; Bazeed et al, 1986; Ziegelbaum et al, 1987; Messing and Catalona, 1998; Goel et al, 2006). When choosing this approach, one needs to be aware of inferior oncologic outcomes. Patients who may benefit from this approach are those with a unifocal low or high-grade tumor in a solitary kidney, synchronous bilateral tumors, and predisposition to form multiple recurrences (Fig. 58-21) (Huffman et al, 1985). The definitive diagnosis, tumor location, and grade should be verified by direct endoscopic visualization and biopsy of the lesion (Gill et al, 1973). Preoperative determination of the stage of UTUC tumors remains difficult (Smith et al, 2011), mainly because of technical limitations of use of small biopsy instruments through the narrow channel of the flexible ureteroscope. Brush biopsy may be used if cup biopsy forceps fail to obtain adequate tissue. The documented risk of wound implantation by tumor is low after open conservative surgery if simple precautions are followed to minimize spillage (Gittes, 1980; Tomera et al, 1982; McCarron et al, 1983). Modern percutaneous antegrade renal surgery allows resection of virtually any lesion formerly treated by open pyelotomy, and the risk of tumor spillage is even lower (see following discussion).

Technique. Usually cross-sectional imaging such as CT or MRI is sufficient for preoperative preparation. In the case of rare hypervascular renal pelvis tumors, renal angiography with embolization of segmental artery may be considered for the ease of identification and tumor removal.

The patient is placed in a flank position. The full flank position with flexion of the table elevates the kidney and provides optimal exposure to the renal hilum and renal pelvis. When the patient is positioned properly on the table, elevation of the kidney rest does not provide any additional benefit with exposure and may cause ischemia to the contralateral kidney (Matin and Novick, 2001). A flank, subcostal, or rarely thoracoabdominal incision is made. An extraperitoneal approach is preferred, but if an extended lymphadenectomy is planned, consideration should be given to transperitoneal surgery. A portion of the 11th or 12th rib may be removed, although it is not usually necessary. Removal of a rib may be helpful in obese patients or in those with a high kidney, with a tradeoff of increased postoperative discomfort. After the incision is completed, similarly to radical nephroureterectomy, the kidney is mobilized to allow identification of the renal hilum. Once the renal vessels are

Figure 58-21. Patient with an invasive tumor of the upper calyx of a solitary kidney. The patient elected an upper pole partial nephrectomy.

exposed and isolated using a vessel loop, the Gerota fascia is opened and the entire kidney is mobilized within it.

To minimize the risk of tumor spillage and seeding, the wound is packed with sponges before an incision is made in urothelium. The renal pelvis is defatted to allow optimal visualization, and a curvilinear incision is made to access the tumor. After excision of the tumor, its base is fulgurated with electrocautery or argon beam. Eventually the pelvis is closed with an absorbable suture, such as 3-0 Vicryl.

The techniques of partial nephrectomy for renal pelvis tumors are essentially the same as for standard open partial nephrectomy, with notable nuances that are not intuitive. For example, the margin of resection is often not visible, as the intrarenal urinary system does not have surface landmarks. Thus, use of intraoperative ultrasound is nearly imperative to accurately determine the margins of parenchymal resection that correspond to the intrarenal urinary system. To minimize tumor seeding, the involved segment of the collecting system is clamped before tumor manipulation. After the excision of the tumor with overlying parenchyma of the kidney, the collecting system defect is closed with an absorbable suture. Parenchymal bleeders are oversewn with a 3-0 Vicryl suture. In addition, argon beam may be used to coagulate the parenchymal surface. Capsular 2-0 Vicryl interrupted or U-stitches are used to approximate the edges of the renorrhaphy bed with or without the use of Surgicel bolsters. Additional hemostatic agents may be used at the discretion of the surgeon. Edges of previously incised Gerota fascia are approximated using a 2-0 Vicryl suture line.

A suction drain is placed in the renal bed in all cases. We do not use a urinary stent routinely, unless there is a suspicion for a ureter stricture downstream.

Results. The reported overall risk of tumor recurrence in the ipsilateral renal pelvis after initial pyelotomy or partial nephrectomy varies from 7% to 60% (Mazeman, 1976; Murphy et al, 1981; Wallace et al, 1981; McCarron et al, 1983; Zincke and Neves, 1984; Ziegelbaum et al, 1987; Messing and Catalona, 1998; Goel et al,

2006). The risk of recurrence after conservative surgery increases with tumor stage from less than 10% for grade 1 to 28% to 60% for grades 2 and 3. The moderate to high risk of recurrence primarily reflects the inherent multifocal atypia and field change of the renal pelvis (Heney et al, 1981; Nocks et al, 1982; Mahadevia et al, 1983; McCarron et al, 1983). The possibility of incomplete initial treatment of the primary tumor cannot be totally excluded.

Estimates of overall and cancer-specific survival after conservative surgery of renal pelvis tumors are hampered by the lack of prospective, controlled, randomized trials and the small numbers of affected patients. The inherent bias introduced by selection of patients for conservative treatment based on medical comorbidities is another variable. Murphy and associates (1980) reported 5-year survival of 75% and 2-year survival of 46% after conservative surgery in patients with grade 1 and grade 2 renal pelvis tumors, respectively. McCarron and associates (1983) reported rates of cures, cancer-related deaths, and deaths from unrelated causes of 33% each in nine patients who underwent conservative surgery. Radical nephroureterectomy and dialysis still offer the best chance of cure and survival in patients with a large, invasive, high-grade, organ-confined renal pelvis tumor (T2N0M0) in a solitary kidney (Gittes, 1980; McCarron et al, 1983). Although the issue of morbidity on hemodialysis is always a concern, for a younger patient with a long life horizon, this risk is minimal in the face of an aggressive high-grade UTUC. Smaller and low-grade tumors may be managed with endoscopic ablation, avoiding the need for open surgery.

Open Segmental Ureterectomy

Ureteroureterostomy

Indications. Segmental ureterectomy is indicated for noninvasive tumors of the proximal ureter or mid-ureter that are not able to be removed endoscopically, or for high-grade or invasive tumors when preservation of renal unit is necessary. Achieving a clear margin and still being able to mobilize enough well-vascularized ureter to perform a tension-free anastomosis is paramount to the success of this procedure and the major limiting challenge.

Technique. The patient is positioned in full or modified flank position. A flank incision from the tip of the 12th rib provides access to the proximal ureter or mid-ureter. With use of an extraperitoneal approach, the ureter is identified, mobilized, and secured with vessel loops. The tumor is palpated, and the ureter is ligated 1 to 2 cm above and below the suspected tumor margin (Fig. 58-22). This location can be also verified by preoperative cross-sectional imaging. The diseased ureter is excised and clear margins ascertained by frozen pathology. After regional lymphadenectomy is performed, both ends of the ureter are spatulated and anastomosed with an interrupted 4-0 Vicryl suture. The success of reconstruction depends on preservation of the blood supply to the ureter and adequate mobilization of the ureteral edges to achieve a tension-free anastomosis. If a large segment of ureter is excised, mobilization and descensus of kidney may be performed to provide additional length to the proximal ureter. A ureteral stent is placed before completion of the anastomosis.

Distal Ureterectomy and Direct Neocystostomy or Ureteroneocystostomy with a Bladder Psoas Muscle Hitch or a Boari Flap

The distal ureterectomy is performed as described in the prior section. The ureter is mobilized to achieve a tension-free anastomosis and spatulated. Ureterovesical anastomosis may be performed using an extravesical or intravesical approach. Whether to perform a refluxing or nonrefluxing anastomosis remains a matter of debate. The benefits of a nonrefluxing anastomosis include limit of infection to the lower tract and the theoretic possibility of avoiding seeding of the upper tract. A refluxing anastomosis may make surveillance of the upper tracts easier. If an extravesical approach is

Figure 58-22. A, Segmental ureterectomy between ties for a large, invasive tumor of the mid-ureter. B and C, Ureteroureterostomy of spatulated ends of the ureter. The repair is performed over an internal stent. D, Completed repair with closed-suction drain in retroperitoneal space.

desired, bladder detrusor muscle is incised, exposing the mucosa. A mucosal slit is performed at the distal aspect of this incision. An anastomosis is performed using continuous or interrupted 3-0 Vicryl sutures through the full thickness of the ureter and bladder mucosa. At the distal portion of the anastomosis, two of these sutures are passed through the full thickness wall of the bladder to anchor the ureter and prevent sliding out of the tunnel. The bladder detrusor is then closed on the top of the ureter with interrupted absorbable sutures, such as 2-0 Vicryl, to achieve a nonrefluxing mechanism. A ureteral stent may be placed before completion of the anastomosis.

For the intravesical technique, an anterior cystotomy is made. An incision is made at the posterolateral wall of the bladder and a 2- to 3-cm submucosal tunnel is fashioned. The ureter is brought through this tunnel. After the ureter is spatulated, the anastomosis is performed with interrupted absorbable sutures.

If a long segment of distal ureter is excised and a tension-free anastomosis cannot be achieved by simple ureteroneocystostomy, an additional 5 cm in length can be gained by using a psoas hitch of the bladder. The bladder is mobilized anteriorly and laterally, and in women the round ligament is divided. The contralateral superior vesical artery can also be divided to gain further mobility. After ureterovesical anastomosis is completed, the ipsilateral dome of the bladder is sutured to the psoas tendon using several interrupted sutures. Care should be taken to avoid injury or entrapment of the genitofemoral nerve.

If additional length is desired, a Boari flap can help gain another 10 to 15 cm in length and in some cases may be able to reach all the way to renal pelvis (Fig. 58-23). If a Boari flap is planned, it is advisable to obtain a preoperative cystogram to assess bladder capacity, because a small-capacity irradiated bladder is a contraindication to this technique. A U-shaped bladder wall flap or, if a longer segment is desired, an L-shaped segment, is developed. To ensure a good blood supply to the flap, the base of the flap should be at least 2 cm greater than the apex. To achieve adequate width of tubularized segment, the width of the flap should be at least three times the diameter of the ureter. The tip of the flap is secured to the psoas muscle using interrupted absorbable suture, and the spatulated ureter is anastomosed to the flap in the end-to-end fashion. The flap is then tubularized and closed with two layers of absorbable sutures. A ureteral catheter is placed before closure of the flap. After all of these techniques, it is advisable to use a suction drain in the retroperitoneum and 7- to 10-day Foley drainage of the bladder. After extensive reconstruction, a cystogram should precede Foley removal.

Ileal Ureteral Replacement

When a long segment of ureter is diseased, a segment of ileum can be used to reconstruct the urinary system. The appendix has also been used for segmental ureteral substitution (Goldwasser et al, 1994). Through a midline intraperitoneal incision, 20 to 25 cm of

Figure 58-23. A, Subtotal ureterectomy required for nephron sparing in a patient with multiple diffuse ureteral tumors. B, A spiral flap is fashioned from the anterior bladder wall. C, The psoas hitch plus Boari flap reaches the remaining proximal ureter. D, Completed anastomosis and bladder closure.

ileum is harvested at least 15 cm away from the ileocecal valve. Bowel continuity is re-established using a stapled anastomosis. With a running absorbable suture, the ileal segment is anastomosed to the renal pelvis proximally in an end-to-end fashion and an isoperistaltic direction. If the proximal portion of the ureter is healthy, the ileal segment can be anastomosed to it in an end-to-side fashion. A ureteral catheter is placed before completion of the anastomosis. Distally, the segment is anastomosed to the posterior wall of the bladder in an end-to-side manner through an intravesical approach. This anastomosis is done in two layers. A suction drain is positioned in retroperitoneum close to anastomotic sites. Optimal drainage is important for proper healing, so a large Foley catheter is inserted in the bladder and left for at least 1 week post-operatively. It may need to be irrigated frequently. A nephrostomy tube may be used to drain the kidney. Before removal of the tubes, a cystogram and nephrostogram are obtained.

In skilled hands, renal autotransplantation is a feasible alternative to ileal replacement. Another approach that may help avoid ileal reconstruction involves mobilization of the kidney with subsequent nephropexy of Gerota fascia to the cut edge of the peritoneum, placing traction in the caudal direction (Fig. 58-24). It may add up to 8 to 10 cm of length on the left side owing to longer left renal vein. This approach has been used laparoscopically, avoiding the need for a second flank incision (Sutherland et al, 2011).

Figure 58-24. Mobilization of the kidney with subsequent nephropexy of Gerota fascia to cut edge of peritoneum, placing traction in the caudal direction, may add up to 10 cm of length on the left side.

Results

In the past, some authors recommended radical nephroureterectomy for all patients with upper tract urothelial tumors (Skinner, 1978). Others suggested segmental ureterectomy only for patients with low-grade, noninvasive tumors of the distal ureter (Babaian and Johnson, 1980). The outcome of patients with UTUC of the ureter strongly correlates with tumor stage and grade regardless of the extent of surgical treatment (Tables 58-4 and 58-5). A single-center study evaluating the prognostic factors in urothelial tumors of the ureter showed an 80% 10-year progression-free survival and 10% ipsilateral tumor recurrence (Lehmann et al, 2007), although the majority of these patients had non-muscle-invasive disease. Overall, 145 patients were evaluated, and 51 underwent segmental ureterectomy. When adjusted for clinicopathologic characteristics, the outcomes were similar for patients who underwent nephroureterectomy versus segmental ureterectomy. The mean follow-up in this study was 96 months. Leitenberger and colleagues (1996) reported their experience with organ-sparing surgery for ureter cancer. Out of 40 patients, 13 underwent extirpative nephron-sparing surgery, and recurrence was observed in 4 patients, all of whom had invasive disease. Anderstrom and colleagues (1989) reported no tumor-related deaths and only 1 recurrence among 21 patients treated with segmental ureterectomy for low-grade, noninvasive ureteral tumors who were observed for a median of 83 months. McCarron and associates (1983) reported 5-year survival of 64% for patients with stage Ta tumors treated by either segmental ureterectomy or endoscopic tumor ablation. In the same series, 5-year tumor-free survival rates were 66% and 50% for stage T1 and T2 tumors, respectively, treated with segmental or distal ureterectomy. In the series by Grabstald and coworkers (1971), disease-specific survival rates were 64% and 100% for stage Ta to T1 and stage T2 disease, respectively. All deaths were from unrelated causes. In contrast, for patients with stage T3 disease, cancer-specific survival was only 7% and the rate of death caused by tumor was 87%. A recent SEER database review of 2044 patients with a mean follow-up of 30 months showed no difference in 5-year cancer-specific mortality in segmental ureterectomy versus nephroureterectomy, adjusted for pathologic stage (Jeldres et al, 2010a).

The risk of ipsilateral recurrence after conservative treatment of ureteral tumors is 33% to 55% (Mazeman, 1976; Johnson and

Lehmann et al, 2007	51	14	96

Babaian, 1979; Babaian and Johnson, 1980; McCarron et al, 1983; Williams, 1991). Most recurrences are distal to the original lesion, but proximal recurrences are also seen (Strong et al, 1976). The risk for recurrence and the need for follow-up are lifelong (Herr, 1998), because late recurrence can be seen (Grossman, 1978). Segmental ureterectomy is offered for low-grade, non-muscle-invasive disease of the proximal ureter or mid-ureter that is not amenable to complete ablation by endoscopic means because of tumor size or multiplicity. Distal ureterectomy and neocystostomy may be offered for low-grade, low-stage, or in select cases, high-grade, locally invasive tumors of the distal ureter when renal preservation is necessary.

Laparoscopic or Robotic Distal Ureterectomy and Reimplantation

Various laparoscopic techniques for distal ureterectomy and reimplantation have been reported (Roupret et al, 2007). The robotic approach may assist with the reconstruction portion of the procedure. The indications are the same as those for the open counterpart, and the techniques are reserved for low-risk distal tumors. The distal ureter is dissected down to the ureteral orifice, and the proximal end is anastomosed to the bladder using standard techniques. The early reports are encouraging, but strict adherence to oncologic principles must be followed.

Endoscopic Treatment

Basic Attributes

Hugh Hampton Young described the first endoscopic evaluation of the upper urinary tract in 1912. Subsequent advances in technology allow us to reach all parts of the urinary tract with minimal morbidity through antegrade and retrograde approaches. Diagnosis and treatment of UTUC have become possible with these improvements because tumor biopsy and ablation by various energy sources are

possible through even the smallest instruments. In addition, miniaturization has made follow-up surveillance of the upper tract more practical with the use of smaller ureteroscopes, which usually do not require previous stenting, or with active dilation of the distal ureter.

Tumors of the upper urinary tract can be approached in a retrograde or antegrade fashion. The approach chosen depends largely on the tumor location and size. In general, a retrograde ureteroscopic approach is used for low-volume ureteral and renal tumors. An antegrade percutaneous approach is preferred for larger tumors of the upper ureter or kidney and for those that cannot be adequately manipulated in a retrograde approach because of location (e.g., lower pole calyx) or previous urinary diversion. In cases with multifocal involvement, combined antegrade and retrograde approaches can be considered (Fig. 58-25).

The basic principles for treatment of UTUC are similar to those for the bladder counterpart (Fig. 58-26). The tumor is sampled and ablated by electrocautery or laser energy sources. A staged procedure should be considered for high-volume disease or disease that is thought to represent high pathologic grade or stage. In such cases, when subsequent nephroureterectomy most likely will be necessary for cure, only biopsy and partial ablation are performed to minimize the risks of perforation or major complications. Endoscopic management is completed only after the pathologic examination shows that the patient is an acceptable candidate for continued minimally invasive endoscopic management. If the pathologic process is unresectable, of high grade, or invasive, the patient should proceed immediately to nephroureterectomy, provided he or she is medically fit. Patients who undergo renal-sparing therapy must be committed to a lifetime of follow-up with radiographs and endoscopy.

Ureteroscopy and Ureteropyeloscopy

The ureteroscopic approach to tumors was first described by Goodman in 1984 and is generally favored for ureteral and smaller renal tumors. With the advent of small-diameter rigid and flexible

Figure 58-25. Patient with synchronous bilateral tumors. **A**, Right renal cell carcinoma that required radical nephrectomy. **B**, Left proximal ureteral tumor that required combined ureteroscopic and antegrade percutaneous ablation.

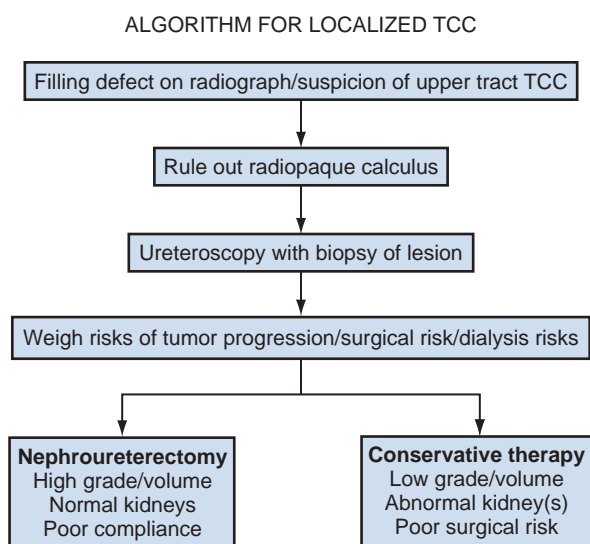

Figure 58-26. Algorithm for endoscopic approach to upper tract transitional cell carcinoma (TCC).

ureteroscopes, tumor location is less of a limiting factor than it used to be. The advantage of a ureteroscopic approach is lower morbidity than that of the percutaneous and open surgical counterparts, with the maintenance of a closed system. With a closed system, nonurothelial surfaces are not exposed to the possibility of tumor seeding.

The major disadvantages of a retrograde approach are related to the smaller instruments required. Smaller endoscopes have a smaller field of view and working channel. This limits the size of tumor that can be approached in a retrograde fashion. In addition, some portions of the upper urinary tract, such as the lower pole

calyces, cannot be reliably reached with working instruments. Smaller instruments limit the ability to remove large tumors and to obtain deep specimens for reliable staging. In addition, retrograde ureteroscopy is difficult in patients with prior urinary diversion.

Technique and Instrumentation. A wide variety of ureteroscopic instruments are available, each with its own distinct advantages and disadvantages. In general, rigid ureteroscopes are used primarily for the distal ureter and mid-ureter. Access to the upper ureter and kidney with rigid endoscopy is unreliable, especially in the male patient. Larger, rigid ureteroscopes provide better visualization because of their larger field of view and better irrigation. Smaller rigid ureteroscopes (8 Fr) usually do not require active dilation of the ureteral orifice (Fig. 58-27A). Newer-generation, flexible ureteropyeloscopes are available in sizes smaller than 8 Fr to allow simple and reliable passage to most portions of the urinary tract (Abdel-Razzak and Bagley, 1993; Grasso and Bagley 1994; Chen and Bagley 2000; Chen et al, 2000). These are generally preferred in the upper ureter and kidney, where the rigid ureteroscope cannot be reliably passed. Flexible ureteroscopes, however, have technical limitations, such as a small working channel, that limit irrigant flow and the diameter of working instruments. Further limitations of flexible ureteroscopy include reduced access to certain areas of the kidney, such as the lower pole, where the infundibulopelvic angle may limit passage of the scope, and prior urinary diversion (Fig. 58-27B).

Endoscopic Evaluation and Collection of Urine Cytology Specimens. Cystoscopy is performed and the bladder inspected for concomitant bladder disease. The ureteral orifice is identified and inspected for lateralizing hematuria. A small-diameter (6.9 or 7.5 Fr) ureteroscope is passed directly into the ureteral orifice, and the distal ureter is inspected before any trauma from a previously placed guidewire or dilation. A guidewire is then placed through the ureteroscope and up the ureter to the level of the renal pelvis under fluoroscopic guidance. The flexible ureteroscope is used to visualize the remaining urothelium. When a lesion or suspicious area is seen, a normal saline washing of the area is performed before

Figure 58-27. A, Rigid ureteroscopic approach. B, Flexible ureteroscopic approach. URS, ureteroscope.

biopsy or intervention (Bian et al, 1995). If the ureter does not accept the smaller ureteroscope, active dilation of the ureter is necessary.

Special circumstances include prior urinary diversion and tumor confined to the intramural ureter. With cases of prior urinary diversion, identification of the ureteroenteric anastomosis is difficult and may require antegrade percutaneous passage of a guidewire down the ureter before endoscopy. The wire can be retrieved from the diversion, and the ureteroscope can be passed in a retrograde fashion. The nephrostomy tract does not need to be fully dilated in this setting. Wagner and associates (2008) described their experience with endoscopic monitoring of patients with ureteral CIS after radical cystectomy. A second type of case is tumor in the intramural ureter. When a tumor protrudes from the ureteral orifice, complete ureteroscopic ablation of the tumor or aggressive transurethral resection of the entire most distal ureter can be done with acceptable results (Palou et al, 2000).

Biopsy and Definitive Treatment. Three general approaches can be used for tumor ablation: bulk excision with ablation of the base, resection of the tumor to its base, and diagnostic biopsy followed by ablation with electrocautery or laser energy sources. Regardless of technique used, special attention to biopsy specimens is necessary. Specimens are frequently minute and should be placed in fixative at once and specially labeled for either histologic or cytologic evaluation (Tawfik et al, 1997).

Ureteroscopic Techniques. The tumor is debulked by use of either biopsy forceps or a flat wire basket engaged adjacent to the tumor (Fig. 58-28A). Next, the tumor base is treated with either electrocautery or laser energy sources. This technique is especially useful for low-grade papillary tumor on a narrow stalk. The specimen is sent for pathology evaluation.

Alternatively, a ureteroscopic resectoscope is used to remove the tumor (Fig. 58-28B). Only the intraluminal tumor is resected, and no attempt is made to resect deep (beyond the lamina propria). Extra care is necessary in the mid-ureter and upper ureter, where the wall is thin and prone to perforation. With larger-volume disease of the distal ureter, Jarrett and associates (1995a) described extensive dilation of the ureter followed by resection with a long standard resectoscope. The tumor is adequately sampled with forceps and sent to the pathology laboratory for diagnostic evaluation. The

tumor bulk is then ablated to its base with laser or electrocautery energy (58-28C and D). Multiple biopsy specimens are often required when small, flexible 3-Fr biopsy forceps are used. Electrocautery delivered through a small Bugbee electrode (2 or 3 Fr) can be used to fulgurate tumors. However, the variable depth of penetration can make its use in the ureter dangerous, and circumferential fulguration should be avoided because of the high risk of stricture formation. More recently, laser energy with either a neodymium:yttrium-aluminum-garnet (Nd:YAG) (Smith et al, 1984; Schilling et al, 1986; Schmeller and Hofstetter, 1989; Carson, 1991) or a holmium:YAG (Ho:YAG) (Bagley and Erhard, 1995; Razvi et al, 1995; Matsuoka et al, 2003; Suoka et al, 2003) source has been popular. Each has characteristic advantages (Fig. 58-29) and can be delivered through small, flexible fibers (200 or 365 μ m) that fit through small, flexible ureteroscopes without significant alteration of irrigant flow or scope deflection. The Ho:YAG laser is well suited for use in the ureter. The tissue penetration is less than 0.5 mm, which allows tumor ablation with excellent hemostasis and minimal risk of full-thickness injury to the ureter. Its shallow penetration may, however, make its use cumbersome with larger tumors, especially in the renal pelvis. Settings most commonly used for the Ho:YAG laser are energy of 0.6 to 1 J with frequency of 10 Hz. The Nd:YAG laser has a tissue penetration of up to 5 to 6 mm, depending on laser settings and duration of treatment. In contrast to the Ho:YAG laser, which ablates tumor, the Nd:YAG laser works by coagulative necrosis with subsequent sloughing of the necrotic tumor. The safety margin is significantly lower and can limit its use in the ureter, where the ureteral wall is thin. Settings most commonly used for the Nd:YAG laser are 15 W for 2 seconds for ablation of tumor and 5 to 10 W for 2 seconds for coagulation.

A ureteral stent is placed for a variable duration to aid with the healing process. Large tumors usually require multiple treatment sessions during several months.

Results. There are no published series of randomized controlled trials comparing endoscopic therapy and nephroureterectomy, and all are case series (level 4 evidence). Multiple series have shown the safety and efficacy of ureteroscopic treatment of UTUC (Daneshmand et al, 2003; Krambeck et al, 2007; Lucas et al, 2008; Thompson et al, 2008; Gadzinski et al, 2010; Cutress et al, 2012). See Table 58-6 for a summary of the largest current series. In a literature

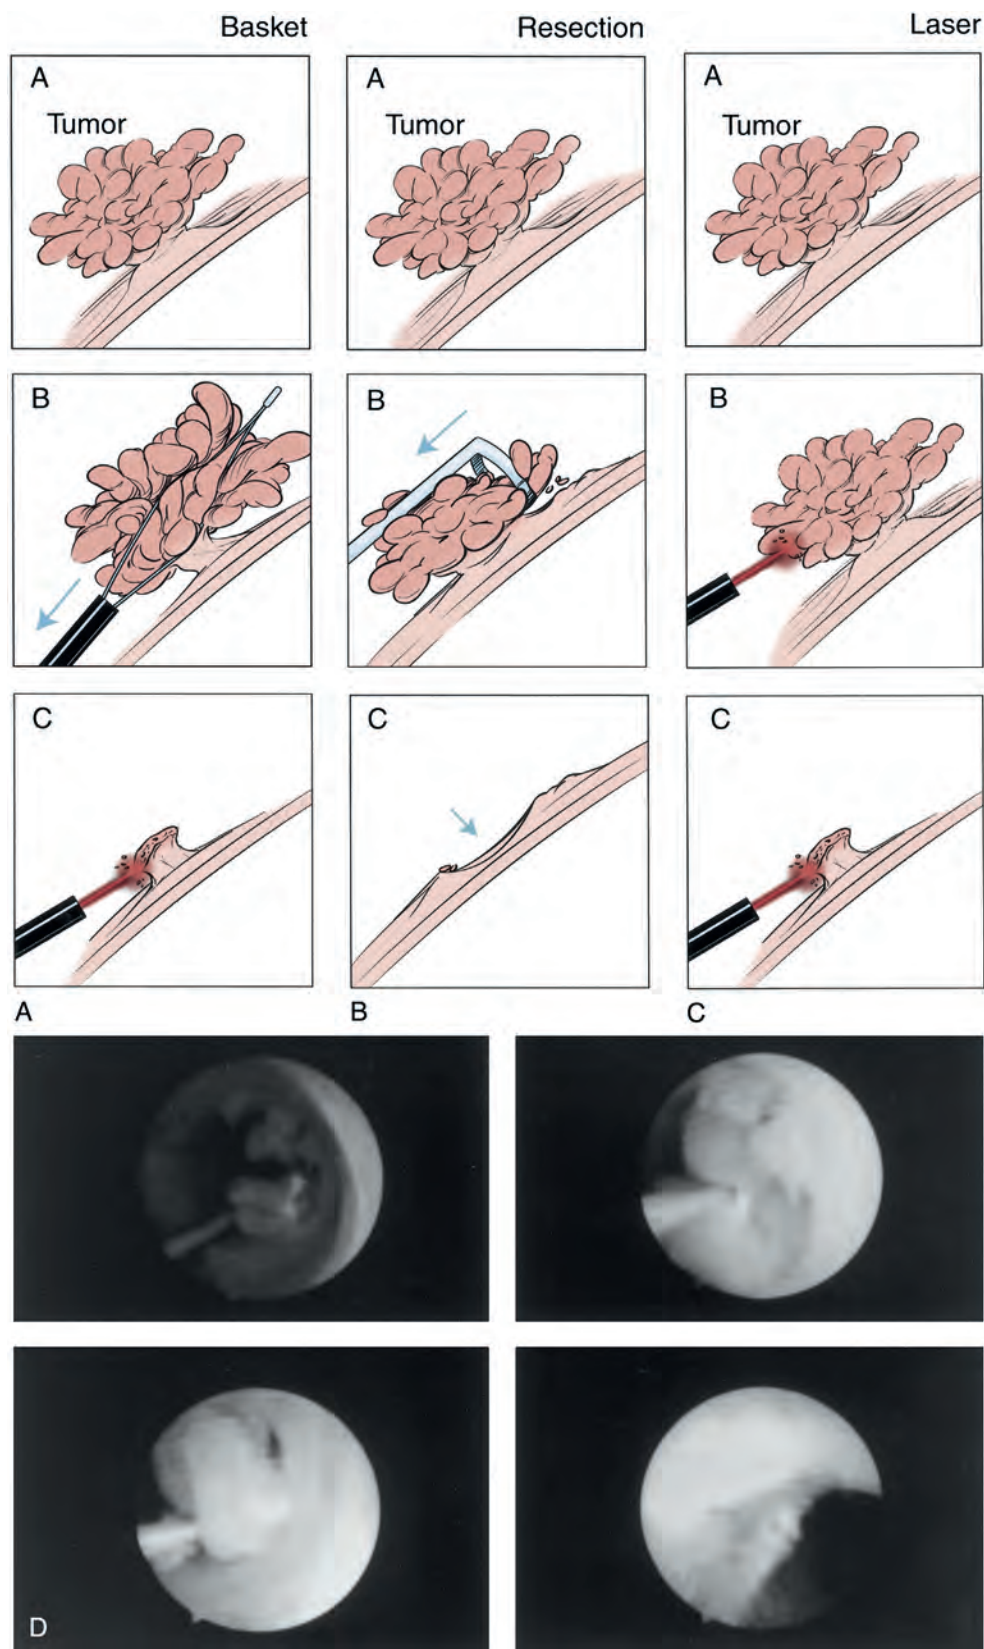

Figure 58-28. Techniques for ureteroscopic treatment of ureteral and renal tumors. **A,** The tumor is identified and removed piecemeal by grasping forceps to its base. **B,** Alternatively, a flat wire basket can be deployed alongside the tumor. The tumor is engaged and removed, with care taken not to avulse the adjacent ureter. With either of these techniques, the base is treated with electrocautery or a laser energy source. **C,** The tumor is identified and removed by a ureteroscopic resectoscope. The technique differs from the technique for bladder tumors in that only intraluminal tumor is resected. No attempt is made to resect deep, as with a bladder tumor. The scope is not arching deep into the tissue. **D,** The tumor is sampled for diagnostic purposes. The bulk of the tumor is then ablated with electrosurgical or laser energy. In general, laser energy is preferred because it has more reliable delivery of energy and depth of penetration. The two most commonly used energy sources are holmium:yttrium-aluminum-garnet and neodymium:yttrium-aluminum-garnet.

Ho:YAG	Minimal penetration (<0.5 mm) Efficient ablation of tumor Precise cutting Setting 0.6-1.2 joules/8-10 Hz
Nd:YAG	Deep penetration (5-6 mm) Excellent hemostasis Tumor ablation by coagulative necrosis Settings: 20-30 watts

Figure 58-29. Characteristics of holmium:yttrium-aluminum-garnet (Ho:YAG) and neodymium:yttrium-aluminum-garnet (Nd:YAG) laser energy sources.

review of 736 patients (Cutress et al, 2012), the overall recurrence rate for the upper tract was 53%, and the risk of bladder recurrence was 34%. Disease progression was present in 15%, with 9% recurrence with metastatic disease. The failure rate of ureteroscopic therapy was 24%, with 19% undergoing subsequent nephroureterectomy. There was, however, considerable bias for favorable tumor characteristics (unifocal, low grade, and small tumor size). As with any urothelial cancer, the most important prognostic indicator for tumor recurrence was grade. Cutress and associates (2012) showed the upper tract recurrence rates for grades 1, 2, and 3 lesions to be 52%, 54%, and 76%, respectively. The upper tract recurrence rate and disease-free survival were both worse with higher-grade tumors.

The literature shows the long-term feasibility of the ureteroscopic approach, but concerns over the high rate of ipsilateral recurrences remain. Daneshmand and colleagues (2003) reported a large number of recurrences with an overall ipsilateral recurrence rate of 90% with three to four recurrences per patient. Cutress and colleagues (2012) reported 5-year recurrence-free survival rates of 13% to 54% in the largest series. This is important in considering patients with a normal contralateral kidney. Patients must be counseled on the need for lifetime follow-up and possible treatment of ipsilateral recurrence.

Complications were uncommon and usually related to the patient's comorbidities. Complications specific to ureteroscopic therapy were 14% (Cutress et al, 2012) and included ureteral perforation, which can be managed with an indwelling ureteral stent, and ureteral stricture, which occurred in 11%. The complication rates seemed to have dropped in more contemporary series, most likely related to smaller endoscopes, improved laser energy sources, and refinements in endoscopic techniques.

Two major concerns of the ureteroscopic approach are the accuracy of ureteroscopic biopsies and the limitations of biopsies, especially with regard to staging. Retrospective reviews of patients who underwent ureteroscopic biopsy followed by nephroureterectomy found the accuracy of ureteroscopic diagnosis to be 89% to 94% and the pathologic grading to match the open surgical technique in 70% to 92% (Keeley et al, 1997a; Guarnizo et al, 2000; Smith et al, 2011). From prior studies, we know that there is a good correlation between grade of lesion and stage (Chasko et al, 1981; Heney et al, 1981). This holds true for the ureteroscopic approach (Keeley et al, 1997c) because 87% of patients with grade 1 or grade 2 tumors had noninvasive disease (stage Ta or T1), whereas 67% of patients with grade 3 tumors had invasive disease (stage T2 or T3). This information supports the notion that tumor grade is the most important prognostic factor; and although stage cannot be directly assessed, noninvasive disease can be expected in most cases of low-grade tumor.

A final concern is whether ureteroscopy promotes progression or spread of disease to other urothelial surfaces or metastatic sites. There have been reports of increased tumor appearance in refluxing ureters of patients with bladder tumors (de Torres Mateos et al, 1987) and in the ipsilateral urinary tract and bladder of patients after ureteroscopic treatment. However, Kulp and Bagley (1994)

reported on 13 patients who underwent multiple ureteroscopic treatments followed by nephroureterectomy; they found no unusual propagation of cancer in the specimens. Concerns that ureteroscopy may promote metastatic spread were raised by Lim and associates (1993), who found tumor cells in renal lymphatics after ureteroscopy. However, Hendin and colleagues (1999) reported no increased risk of metastatic disease in a group of patients who underwent ureteroscopy before nephroureterectomy compared with a group undergoing nephroureterectomy alone.

Percutaneous Approach

The percutaneous approach was first described by Tomera and coworkers in 1982 and is generally favored for larger tumors located proximally in the renal pelvis or proximal ureter. The main advantage of the percutaneous approach is the ability to use larger instruments that can remove a large volume of tumor in any portion of the renal collecting system. Because deeper biopsy specimens are obtained, tumor staging as well as grading is usually possible. In addition, a percutaneous approach may avoid the limitations of flexible ureteroscopy, especially in complicated calyceal systems or areas difficult to access, such as the lower pole calyx or the upper urinary tract of patients with urinary diversion. With a percutaneous approach, the established nephrostomy tract can be maintained for immediate postoperative nephroscopy and administration of topical adjuvant therapy.

The main disadvantages are the increased morbidity compared with ureteroscopy and the potential for tumor seeding outside the urinary tract. Establishment of the nephrostomy tract has inherent risks, and the procedure usually requires inpatient admission. Distinct risks related to a percutaneous approach are loss of urothelial integrity and exposure of nonurothelial surfaces to tumor cells. This open system provides the possibility of tumor implantation in the nephrostomy tract.

Technique and Instrumentation

Establishment of the Nephrostomy Tract. Cystoscopy is performed, and an open-ended ureteral catheter is positioned in the pelvis. Contrast material is injected to define the calyceal anatomy, and a percutaneous nephrostomy tract is established through the desired calyx (Fig. 58-30). If the patient is in the prone split leg position, a flexible ureteroscope can be passed to the desired area and renal access obtained under direct and fluoroscopic guidance. Tumors in peripheral calyces are best approached with direct puncture distal to the tumor (Fig. 58-31), avoiding trauma to or direct puncture into the tumor. Disease in the renal pelvis and upper ureter is best approached through an upper or middle pole access to allow scope maneuvering through the collecting system and down the ureteropelvic junction. The tract is dilated by either sequential (Amplatz) or balloon dilation to accommodate a 30-Fr sheath. Correct positioning of the nephrostomy tract is crucial to the success of the procedure and should be done by the urologist or by the radiologist after direct consultation with the operating surgeon. Some practitioners prefer to perform this in two stages, with establishment of a tract first and allowing this to mature over 1 to 2 weeks, followed by tract dilation and treatment. Alternatively, if only a diagnostic procedure needs to be performed, such as evaluation of positive cytology findings after cystectomy and diversion, one may also use the initial smaller nephrostomy tract to introduce a flexible ureteroscope. Otherwise, a nephroscope is inserted, and the ureteral catheter is grasped, brought out the tract, and exchanged for a stiff guidewire, thus providing both antegrade and retrograde control. Complete nephroscopy is performed with rigid and flexible endoscopes when necessary. Any suspicion of upper ureteral involvement warrants antegrade ureteroscopy.

Biopsy and Definitive Therapy. After identification, the tumors are removed by one of the following four techniques (Fig. 58-32). In the first technique, which uses cold-cup biopsy forceps through a standard nephroscope, the bulk of the tumor is grasped by forceps and removed in piecemeal fashion until the base is reached (see Fig. 58-32A). A separate biopsy of the base is performed for staging purposes, and the base is cauterized with a Bugbee electrode and

Modified from Cutress ML, Stewart GD, Zakikhani P, et al. Ureteroscopic and percutaneous management of upper tract urothelial carcinoma (UTUC): systematic review. BJU Int 2012;110:614–28.

Figure 58-30. Nephrostomy tract puncture site. Position of the nephrostomy is imperative for successful percutaneous resection of transitional cell carcinoma of the renal collecting system and upper ureter and requires careful preoperative evaluation of radiographs for tumor location. Tumors in peripheral calyces (A to C) are best approached by direct puncture as far distally in the calyx as possible. Tumors in the renal pelvis (D) and upper ureter (E) are best approached by puncture to an upper (1) or middle (2) calyx, which allows the scope to be maneuvered in the renal pelvis and down the ureter. Tumors in the lower calyx are approached by lower calyx puncture (3).

cautery. Low-grade papillary lesions on a thin stalk are easily treated in this manner with minimal bleeding.

Alternatively, a cutting loop from a standard resectoscope or bipolar resectoscope is used to remove the tumor to its base (see Fig. 58-32B). A monopolar resection does carry the risk of absorption of large volumes of hypo-osmotic irrigant, and thus bipolar resection may be preferred. Once again, the base should be resected and sent separately for staging purposes. This approach is more effective for larger, broad-based tumors for which simple debulking to a stalk is not possible.

For the third technique, which uses flexible or rigid endoscopes, the tumor is sampled and treated with Ho:YAG or Nd:YAG laser at 25 to 30 W (Fig. 58-32C and D). Tissue may also be obtained with a small snare used for gastrointestinal polyps.

Regardless of approach, a nephrostomy tube is left in place. This access can be used for second-look follow-up nephroscopy to ensure complete tumor removal (Fig. 58-33). Nephroureterectomy is indicated if the pathologic examination shows high-grade or invasive disease.

Second-Look Nephroscopy. Follow-up nephroscopy is performed 4 to 14 days later to allow adequate healing. The tumor resection site is identified, and any residual tumor is removed. If no tumor is identified, the base should be sampled and treated by cautery or the Nd:YAG laser (15 to 20 W and 3-second exposures). The nephrostomy tube can be removed several days later if all tumors have been removed. If the patient is being considered for adjuvant topical therapy, a small, 8-Fr nephrostomy tube is left to provide access for instillations. Some authors advocate third-look nephroscopy before removal of the nephrostomy tube (Jarrett et al, 1995b).

Results. As with the ureteroscopic approach, there are no randomized controlled trials and only limited contemporary case series (Table 58-7) with adequate numbers and follow-up from which to draw reasonable conclusions (Goel et al, 2003; Palou et al, 2004; Roupret et al, 2007; Rastinehad et al, 2009). In a literature review of 288 patients, Cutress and colleagues (2012) found an overall rate of upper tract recurrence of 26% and a bladder recurrence rate of 31%. Failed endoscopic management occurred in 32% with a nephroureterectomy rate of 22%. Disease progression occurred in

Figure 58-31. A, Retrograde pyelogram of a man with transitional cell carcinoma of the lower calyx in a solitary kidney. B, Access distal in the calyx allows a clear view of the tumor. C, Subsequent resection.

Figure 58-32. Techniques for percutaneous removal of transitional cell carcinoma of the renal collecting system. A, The tumor is identified and debulked by forceps to its base. The base is sampled and sent separately for evaluation. This technique works well for papillary tumors on a narrow stalk. Broad-based tumors may cause excessive bleeding and are best approached with resection or laser therapy. B, With use of a standard resectoscope the tumor is identified and resected to its base. Special care should be taken to avoid resection into major renal vasculature. The tumor is identified, sampled for diagnostic purposes, and treated by holmium or neodymium laser sources. This can be done through a standard nephroscope (C) or with a flexible cystoscope (D).

17%, with 6% going on to develop metastatic disease. As expected, tumor grade strongly predicted outcomes. [Cutress and associates \(2012\)](#) showed the upper tract recurrence rate for grades 1, 2, and 3 lesions to be 23%, 30%, and 40%, respectively. [Lee and colleagues \(1999\)](#) reviewed their 13-year experience with percutaneous management, comparing 50 patients who underwent percutaneous management with 60 patients who underwent nephroureterectomy, and found no significant difference in overall survival. As expected, patients with low-grade disease did well regardless of modality and

patients with high-grade disease did poorly regardless of treatment option.

Most would agree from the literature that percutaneous management is acceptable in patients with low-grade (grade 1) disease regardless of the status of the contralateral kidney, provided the patient is committed to lifelong endoscopic follow-up. Patients with high-grade or grade 3 disease do poorly regardless of modality chosen but should probably undergo nephroureterectomy to maximize cancer therapy (provided they are medically fit). The

Figure 58-33. A, A 65-year-old man with a solitary kidney and a 5-cm renal pelvis tumor. B, Nephrostogram after patient underwent staged resection. C, Three-month follow-up retrograde pyelogram after completed resection. The patient showed grade 1 transitional cell carcinoma without invasion to submucosa.

largest area of controversy surrounds the use of percutaneous management for patients with grade 2 disease and a normal contralateral kidney. [Jabbour and associates \(2000\)](#) retrospectively evaluated 24 patients and found a disease-specific survival of 95% overall and 100% and 80% for stage Ta and stage T1 lesions, respectively. This study shows an acceptable result with conservative treatment of noninvasive grade 2 disease. With more invasive lesions, the potential for disease progression and metastatic disease is significant and nephroureterectomy should be considered.

Complications from percutaneous management of tumors are similar to those for benign renal processes and include bleeding, systemic absorption of hypo-osmotic irrigation (with monopolar resection), perforation of the collecting system, and secondary ureteropelvic junction obstruction. Cutress showed the overall complication rate to be 27% with transfusion, dialysis and renal failure being the most significant. Complications increase in number and severity with higher tumor grade ([Jarrett et al, 1995a](#)). This finding is probably a result of the more extensive pathologic process and treatments necessary to eradicate the tumor. Unlike ureteroscopic resection, the percutaneous method can stage tumors, and, as expected, stage increases with tumor grade.

A major concern of the percutaneous approach is the potential seeding of nonurothelial surfaces with tumor cells. There have been multiple reported cases of nephrostomy tract infiltration with high-grade tumors ([Tomera et al, 1982](#); [Slywotzky and Maya, 1994](#); [Huang et al, 1995](#); [Oefelein and MacLennan, 2003](#); [Treuthardt et al, 2004](#)). [Cutress and colleagues \(2012\)](#), however, showed only a 0.3% overall rate of tumor seeding. Tract seeding is a possibility but appears to be an uncommon event.

Management of Positive Upper Tract Urinary Cytology or Carcinoma in Situ

Evaluation

An unequivocal positive voiding urinary cytology usually indicates presence of urothelial carcinoma. Most cases are from a bladder source; however, extravesical sites may be involved, including the

upper urinary tracts and the prostatic urethra in men. Often, the diagnosis is difficult owing to the limitations of radiographic evaluation of upper tracts and the complexity of upper tract endoscopy compared with the bladder. In addition, the interpretation of minute pathologic specimens of the upper urinary tract makes precise histologic diagnosis and staging difficult. [Figure 58-34](#) outlines the algorithm for management of a positive urinary cytology as described by [Schwalb and associates \(1994\)](#). One must first repeat the cytology to confirm the findings. The next step involves radiographic evaluation of the upper tracts, usually with CT urography and a complete bladder evaluation including biopsies and tumor resection if tumor is present. If the bladder evaluation was positive for urothelial carcinoma, the initial treatment at that point is to treat the bladder with either intravesical therapy and/or tumor resection and follow the voided urinary cytologies. If these remain positive despite a negative bladder evaluation or after successful treatment of the bladder, then one should proceed to evaluating extravesical sites. If the initial bladder evaluation was negative, then one may proceed directly to evaluation of extravesical sites. Evaluation of extravesical sites should include selective cytologies from each upper urinary tract, ensuring noncontamination of the specimen from the bladder or urethra, as well as resection of a representative specimen of the prostatic urethra in men. Selective cytologies should preferably be done, along with ureteroscopy, to allow for direct visualization of the upper urinary tracts.

Carcinoma in Situ of the Upper Urinary Tracts

The diagnosis of CIS of the upper urinary tracts is a difficult one because of the inability to evaluate the urothelium of the upper tracts with adequate tissue samples. In most cases the diagnosis is one of exclusion wherein there is a persistent positive selective cytology in the absence of any ureteroscopic or radiographic findings. Treatment is not well established: Radical nephroureterectomy was performed in the past for a unilateral cytologic abnormality of the upper tract to eliminate presumed CIS. This practice is not recommended ([Gittes, 1980](#); [McCarron et al, 1983](#); [Williams, 1991](#); [Messing and Catalona, 1998](#)). Upper tract cytology suffers

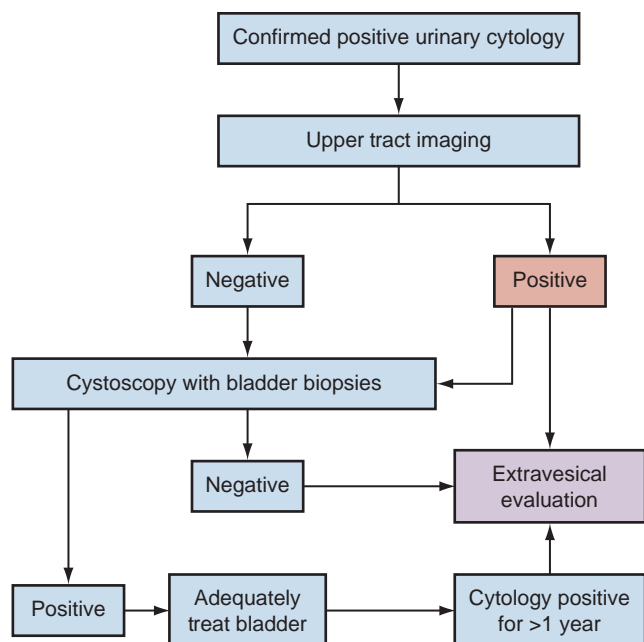

Figure 58-34. Algorithm for management of a positive urinary cytology.

from the same limitations in specificity as does bladder cytology. Furthermore, properly collected upper tract samples are of limited volume and cell count compared with bladder washings. Any source of inflammation, such as urinary infection or calculus, may produce a false-positive result. A subsequent cytologic abnormality from the contralateral side during follow-up is not rare in cases of true-positive results from early CIS (Murphy et al, 1974; Khan et al, 1979). There is one large series and many small series of topical therapy of the upper tract with immune therapy and chemotherapy via retrograde and antegrade approaches with variable response rates. Patients with CIS appear to do equally as well as their bladder counterparts in these limited, retrospective studies (Giannarini et al, 2011) (see section on topical therapy). Placement of a nephrostomy tube seems to be the more reliable delivery system. Most would not intervene initially with surgical intervention in the absence of any histologic, radiographic, or endoscopic finding owing to the limitations of cytology alone with false-positive results and the high risk for bilateral disease in the future. In addition, segmental resection is usually not effective in addressing the problem because of the multifocality of the disease. Nephroureterectomy is, however, indicated if one can confirm radiographically or endoscopically that the patient has more than just surface disease. Frequent-interval re-evaluation with urinalysis, bladder and possible selective cytology, cystoscopy every 3 months, and retrograde pyelography or ureteropyeloscopy every 6 months is indicated for 1 to 2 years.

Another scenario is CIS of ureteral margins during radical cystectomy. There is controversy over the proper management of this finding, which definitely confers a risk of disease progression. However, many do not progress, and when they do, recurrences may not be isolated to the distal ureteral margin. Wagner and colleagues (2008) studied a select group with serial endoscopy and found that recurrences were found at the site of the margin but also at other sites. Herr and colleagues (1996) showed that many did not show any tumor at the margin site but did show a high risk of overall disease progression to death from metastatic disease.

Adjuvant Therapy

After Organ-Sparing Therapy

Any procedure short of extirpative surgery has a higher local recurrence owing to the established risk of ipsilateral recurrence. Several

Figure 58-35. Setup for administration of topical immunotherapy or chemotherapy to the upper urinary tract through a previously placed nephrostomy tube. Therapy is instilled by gravity with a mechanism that prevents excessive intrarenal pressures. High pressures have been linked to complications of systemic absorption and bacterial sepsis. MMC, mitomycin C.

approaches are available to minimize these risks. They fall into two basic categories: instillation of immunotherapeutic or chemotherapeutic agents, and brachytherapy of the nephrostomy tract.

Instillation Therapy. Instillation therapy is used in two settings for treatment of UTUC, namely as primary treatment for CIS and as adjuvant therapy after endoscopic or organ-sparing therapy. Delivery of the agents presents an additional challenge and can be accomplished in several ways. Accepted techniques include antegrade instillation through a nephrostomy tube (Fig. 58-35) and retrograde instillation directly into a ureteral catheter. Attempting to induce reflux in a patient using an indwelling ureteral stent or by iatrogenically created vesicoureteral reflux appears to be an unreliable method of effective drug administration to the upper tracts. Patel and Fuchs (1998) described a convenient technique of outpatient instillation through a ureteral catheter placed suprapubically, but given the concern over tumor implantation, this technique is rarely used. Regardless of the technique chosen, administration to the upper urinary tract should be done under low pressure and in the absence of active infection to minimize the risk of bacterial sepsis or systemic absorption of the agent.

Results. The same agents used to treat urothelial carcinoma of the bladder are used to treat tumors of the upper urinary tract. Most historical studies have described small, retrospective, uncontrolled series of patients undergoing therapy with thiotepa (Elliott et al, 1996; Patel et al, 1996), mitomycin (Cornu et al, 2010; Cutress et al, 2012), and BCG (Palou et al, 2004). See Table 58-8 for a summary.

Gemcitabine has been used intravesically as an alternative to BCG with fewer side effects. We may see a larger role in the upper urinary tract. Although the cumulative experience appears encouraging, definitive conclusions are not easily reached. Possible reasons for this include (1) insufficient numbers to show clinical significance because of the relative rarity of the disease; (2) tumors of the upper urinary tract, which have a tumor biology different from that of their bladder counterparts; and (3) a nonstandardized and possibly inadequate delivery system that, unlike in the bladder, does not allow uniform delivery of the agent with adequate dwell time to enable a clinical response.

The largest experience is from use of BCG via a nephrostomy tube for primary treatment of CIS, and in this setting favorable responses are seen. In a recent update of this experience with 55 patients, a 57% 5-year recurrence-free survival was seen; on the

other hand, patients treated in adjuvant fashion after endoscopic ablation had inferior results (Giannarini et al, 2011). The greatest experience with chemotherapy is with the use of mitomycin C, but because of the smaller numbers of patients and variable selection criteria, no definite conclusions can be reached, with the exception that mitomycin is very well tolerated and has a very low adverse event profile (Audenet et al, 2013).

In the study with intrarenal perfusion of BCG, despite initial return of cytology results to normal, 50% of patients (5 of 10) developed disease recurrence after a mean follow-up of 50.9 months, and all of these had cancer-specific mortality (Hayashida et al, 2004). The initial results regarding response are encouraging; however, the recurrences with possible disease progression should not give the clinician optimism for long-term cure. Although removal of a renal unit for CIS alone is not urged, patients need to be followed vigilantly for disease progression.

The most common complication of instillation therapy is bacterial sepsis. To minimize this problem, patients must be evaluated for active infection before each treatment, and only a low-pressure delivery system should be used. Agent-specific complications of the various therapies include ramifications of systemic absorption of the agent. Bellman and colleagues (1994) described upper urinary tract complications of percutaneous BCG instillation. Granulomatous involvement of the kidney in the absence of systemic signs of BCG infection was most commonly seen. Mukamel and associates (1991) saw an inordinate decrease in renal function for patients receiving BCG who had vesicoureteral reflux.

Brachytherapy. Brachytherapy to the nephrostomy tract through iridium wire or delivery system was described by Patel and coworkers (1996) and Nurse and colleagues (1989). There were no instances of tract recurrences in this series, although the authors acknowledged the rarity of the event. The only major complication attributed to the brachytherapy was cutaneous fistula formation requiring nephroureterectomy.

After Complete Excision

Radiation Therapy. The rationale for focal radiation therapy is to decrease the risk of local relapse after radical surgery for locally

advanced non-organ-confined disease (stage T3 to T4, N+). Most series concluding that postoperative irradiation is beneficial are small or even anecdotal, uncontrolled, and retrospective (Holtz, 1962; Brady et al, 1968; Leiber and Lupu, 1978). In one series with 41 patients, postoperative radiation therapy decreased local recurrence but had no effect on distant relapse or survival (Brookland and Richter, 1985). Maulard-Durdux and associates (1996) retrospectively reviewed 26 patients who received 46 Gy to the wound bed after radical surgery for upper tract tumors. Tumors were grade 2 in 40% and grade 3 in 60% of patients. Tumor stage was T2, T3, and N+ in 42%, 58%, and 35% of cases, respectively. Five-year survival is shown in Table 58-3. Overall 5-year survival was 49%, with 30% remaining disease free. All patients with local relapse also had distant relapse, leading the authors to conclude that adjuvant radiation therapy is not beneficial.

The largest experience addressing this issue is that reported by Hall and associates (1998b). A retrospective review of 252 patients with upper tract tumors who were observed for a median of 64 months was performed. Radical nephroureterectomy was performed in 77% of patients. Initial tumor stage was T3 in 19% and T4 in 10% of patients; 50% and 52%, respectively, of patients with stage T3 and stage T4 tumors received 40 Gy to the wound bed postoperatively. Disease-specific and overall 5-year survival rates were 41% and 28%, respectively, for patients with stage T3 disease. Actuarial 5-year disease-specific survival rates for stage T3 with or without adjuvant radiation therapy were 45% and 40%, respectively. Median survival was 6 months for stage T4 disease. There were no long-term survivors in this group. Local relapse occurred in only 9% of the entire series and was seen only in patients with stage T3 and stage T4 disease. Among the patients who received adjuvant radiation, isolated local relapse without distant metastases occurred in only 10% and 4% of stage T3 and stage T4 cases, respectively.

Czito and colleagues (2004) retrospectively analyzed the cohort of 31 patients with advanced disease (T3 or T4 and/or N+) disease who received adjuvant radiation with or without chemotherapy. Most of these patients had undergone nephroureterectomy, and 5 patients had residual gross disease after surgery. After administration of two to four cycles of MVC (methotrexate-vinblastine-cisplatin), 9 patients received radiation with concurrent cisplatin

administration. The other 22 patients were treated with radiotherapy only. The mean dose of radiation was 46.9 Gy, and the group that received chemotherapy had a larger proportion of patients with adverse pathologic features, such as higher stage and grade. On univariate analysis, there was an observed improved 5-year overall and disease-specific survival with the use of chemotherapy. Thus **radical nephroureterectomy alone provides a high rate of local control. Adjuvant radiation without chemotherapy for high-stage disease does not protect against a high rate of distant failure. There may be a role for combined radiation-chemotherapy regimens in patients with advanced disease with adverse features; however, the current evidence supporting this is small and retrospective in nature.**

Systemic Chemotherapy. The use of agents for UTUC has been extrapolated from chemotherapy regimens used in bladder urothelial cancer. There are no randomized trials evaluating the effects of neoadjuvant or adjuvant chemotherapy on patients with UTUC, and the small number of cases treated with adjuvant chemotherapy precludes definitive conclusions of efficacy.

The strongest current argument is for use of neoadjuvant therapy, because many patients have baseline chronic kidney disease, which worsens after nephroureterectomy, rendering them ineligible to receive the full-dose cisplatin-based chemotherapy (Lane et al, 2010). There are two reports on the use of neoadjuvant therapy. The initial data came from a small series of 15 patients who received MVAC (methotrexate, vinblastine, Adriamycin, and cisplatin), MEC (methotrexate, etoposide, and cisplatin), or MVEC (methotrexate, vinblastine, epirubicin, and cisplatin) regimens before nephroureterectomy (Igawa et al, 1995). All of the patients had advanced disease, with 6 having T2N0M0, 4 with T3N0-1M0 and 5 with T4N0-3M0. Of these patients, 13% achieved complete, and 40% partial, pathologic response. The authors reported a positive correlation between pathologic response and disease-specific survival. Another retrospective case-control study (Matin et al, 2010) of 150 high-risk UTUC patients, 43 of whom received neoadjuvant therapy with a variety of regimens (MVAC, cisplatin-gemcitabine-ifosfamide [CGI], gemcitabine-paclitaxel-doxorubicin [GTA], cisplatin-gemcitabine [GC], and others), observed a significant incidence of pathologic downstaging of tumors and a 14% complete response rate. A recent update of these patients showed significant improvement in 5-year survival in those receiving neoadjuvant chemotherapy versus a matched historical cohort (94% vs. 58%, $P < .001$) (Porten et al, 2013).

Adjuvant therapy is used infrequently in the treatment of UTUC, and most publications are based on retrospective review of institutional experience. A study of 27 patients with pT3N0M0, 16 of whom received platinum-based therapy after nephroureterectomy, reported no significant difference in recurrence-free and disease-specific survival after 40 months of follow-up (Lee et al, 2006). Another study compared the outcomes of 24 patients with pT2-3N0M0 disease who received MVAC chemotherapy after nephroureterectomy with those of a similar group of patients who did not receive adjuvant therapy. The authors did not observe a significant difference in 10-year overall survival rates. A multi-institutional retrospective review of pT3-4N0M0 and N+ patients (Hellenthal et al, 2009) who did or did not receive platinum-based chemotherapy failed to show a significant difference in the overall or disease-specific survival rates. However, in this cohort, adjuvant therapy was more commonly used in patients with higher tumor grade and stage. In contrast, Kwak and colleagues (2006) showed a twofold decrease in recurrence of cancer and a significant reduction in disease-specific mortality (28.1% vs. 81.8%) in the pT2-3N0M0 patient population who received platinum-based chemotherapy. **In summary, to date there is a lack of controlled trials that establish the efficacy of either neoadjuvant or adjuvant chemotherapy in this UTUC. However, given the significant influence of renal function on eligibility to receive effective chemotherapy, the focus is shifting toward a neoadjuvant approach, with several trials underway at the time of this writing. Further studies are needed to aid in providing recommendations in this setting.**

Treatment of Metastatic Disease

There are limited data on efficacy of chemotherapy in metastatic UTUC. Prospective randomized trials comparing chemotherapeutic regimens for UTUC are not feasible owing to the rarity of these patients. Therefore the data for chemotherapy response rates for upper tract disease are extrapolated from observations in urothelial cancer, most of which do not stratify results by original location of tumor. In a study of 184 patients accrued over three consecutive time intervals from 1986 to 2004 at MD Anderson Cancer Center, the median recurrence-free survival was 2.4 years and did not improve over time (Brown et al, 2006). The decline in renal function after nephroureterectomy in these mostly elderly patients may compromise the ability to administer effective postoperative chemotherapy and is yet another reason to consider neoadjuvant chemotherapy for patients with high-risk upper tract tumors. When there is evidence of regional lymph node metastases, initial chemotherapy should be given as the primary therapy, and surgery should be withheld until a good—ideally a complete—radiographic response is seen. At that time, consolidative surgery can be offered, similar to the paradigm for bladder urothelial carcinoma.

The MVAC regimen continues to have the highest response rate (Sternberg et al, 1989); however, its toxicity prohibits optimal dosage and duration in a large proportion of patients. In addition, complete responses are rare in the metastatic setting, and the duration of response is limited, with overall survival of 12 to 24 months. For all these reasons there is considerable ongoing investigation with newer agents, including paclitaxel, ifosfamide, carboplatin, gemcitabine, and vinflunine, used in various combinations and sequences (Roth et al, 1994; Bajorin et al, 1998; Redman et al, 1998; Vaughn et al, 1998; Kaufman et al, 2000; Lorusso et al, 2000; Bamias et al, 2006; Vaughn et al, 2009; Siefker-Radtke et al, 2013). Carboplatin is frequently substituted for cisplatin because of either limitations of renal function or concerns over toxicity with the latter, but the results with carboplatin remain inferior (Galsky et al, 2012). Many of these show initial overall response rates similar to the response rate to the MVAC regimen and lower toxicity. However, thus far, complete responses are rare, and there are no head-to-head comparison studies evaluating their durability or survival advantage compared with the MVAC regimen. A variation of standard MVAC is the dose-dense regimen, whereby all drugs are given at the same time with cell support, and this regimen has actually been shown to have a lower toxicity profile and may have better responses (Sternberg et al, 2006).

Results from a recent randomized phase III study comparing paclitaxel, cisplatin, and gemcitabine (PCG) versus gemcitabine and cisplatin (GC) in chemotherapy-naïve patients with metastatic or locally advanced urothelial cancer (Bellmunt et al, 2012) showed that after a median follow-up of 4.6 years, with addition of paclitaxel, there was improvement in median overall survival (15.8 months vs. 12.7 months). The overall response rate was 55.5% with the use of PCG and 43.6 with GC, and both of the regimens were well tolerated. Of the 626 patients in this cohort, 82 had primary carcinoma of the renal pelvis or ureter; although there was no specific breakdown of the outcomes for this group of patients, on post hoc analysis the overall survival benefit was more pronounced in the group of patients with primary bladder tumors.

There have been encouraging early results with cabozantinib, the inhibitor of MET and VEGF pathways, in patients in whom previous chemotherapy has failed (Fig. 58-36). The patient accrual portion of a phase II trial is ongoing; it is hoped that this trial will provide further insight into the effects of this drug, which has shown clinical activity in multiple solid tumors. Recently, immune modulation using a variety of checkpoint inhibitors has shown promise in the treatment of multiple malignancies, including urothelial carcinoma. Targeting the inhibitory surface receptor PD-1, activation of which by PD-L1 ligand confers inhibition of T-cell proliferation and cytokine production, has produced remarkable clinical activity in phase I trials in metastatic urothelial carcinoma (Plimack et al, 2014; Powles et al, 2014) with favorable side effect profile, and most importantly, infrequent renal impairment. Currently there are

Figure 58-36. A, A patient with urothelial cell carcinoma of the kidney and left inguinal lymphadenopathy. B, The patient had a sustained almost complete response at 9 weeks and 16 weeks after treatment with cabozantinib. Red arrowhead points to resolving adenopathy.

- Physical examination, urine cytology (only for high-grade lesions), and cystoscopy
 - Every 3 months—first year
 - Every 6 months thereafter—years 2 through 3
 - Yearly—thereafter
- Contralateral imaging (IVU or retrograde pyelography)—yearly
- Ipsilateral endoscopy (patients undergoing organ-sparing therapy)—
 - Every 6 months—first several years
 - Yearly—thereafter
- Metastatic evaluation—necessary in all patients with significant risk of disease progression (i.e., high grade or invasive disease)
 - Physical examination, chest x-ray, comprehensive metabolic panel with liver enzymes
 - Every 3 months—first year
 - Every 6 months—years 2 through 3
 - Yearly—years 4 and 5
 - After 5 years—evaluation of urothelium only
 - Computed tomography or MRI of abdomen and pelvis—
 - Every 6 months—years 1 and 2
 - Yearly—years 3 through 5
 - Bone scan—only for elevated alkaline phosphatase level or symptoms of bone pain

Figure 58-37. Follow-up begins after open surgery or when the patient is rendered tumor free by endoscopic management. The commencement of follow-up may be altered according to the potential for disease progression. IVU, intravenous urography.

ongoing phase II and III trials investigating efficacy of these agents against commonly used chemotherapeutics as a second-line therapy, with the results expected to be reported by 2017 (Wu et al, 2015). Even though to date no single study has specifically addressed the effect of checkpoint inhibition in the upper tract urothelial tumors, we are hopeful that this information is forthcoming.

In summary, UTUC, like bladder cancer, is chemosensitive, but established chemotherapy regimens are toxic and lack sustained response. Unique to this population is the high rate of baseline chronic kidney disease, which worsens after nephroureterectomy. It is hoped that continuous advancement in development of novel targeted therapies and experimentation with new chemotherapeutic regimens will help optimize the treatment of metastatic UTUC.

FOLLOW-UP

Issues in Assessing for Recurrence

The propensity of upper tract tumors for multifocal recurrence and metastatic spread with more dysplastic lesions makes follow-up complicated. Postoperative evaluation must routinely include eval-

uation of the bladder, the ipsilateral (if organ-sparing therapy was chosen) and contralateral urinary tracts, and the extraurinary sites for local and metastatic spread. A follow-up regimen is thus dependent on the time from surgery, the approach chosen (organ sparing vs. radical), and the potential for metastatic spread. General recommendations for time intervals are listed in Figure 58-37.

General Procedures

All patients should be assessed at 3-month intervals the first year after they are rendered tumor free by endoscopic or open surgical approaches (Keeley et al, 1997a). After the first year, this evaluation can be spaced out. This schedule is largely based on work with bladder urothelial carcinoma, showing that most tumor recurrences after bladder resection develop in the first year (Varkarakis et al, 1974; Loening et al, 1980). The upper urinary tract is more difficult to monitor, and delayed recognition of upper tract tumor recurrence may lead to disease progression and poor results (Mazeman, 1976). Evaluation should include history, physical examination, urinalysis, and office cystoscopy because of the high risk of bladder recurrences in patients treated both conservatively and with nephroureterectomy (Mazeman, 1976). If the patient requires endoscopic evaluation of the upper urinary tract, cystoscopy can be done in conjunction with that procedure.

Urine cytology may be helpful in assessing for upper tract recurrence, especially for high-grade tumors (Murphy et al, 1981). The usefulness, however, is decreased with less dysplastic tumors (Grace et al, 1967; Sarnacki et al, 1971; Zincke et al, 1976). The same tumor markers under study for bladder urothelial carcinoma are promising for UTUC (Brown, 2000). One marker that may be preferentially more involved in UTUC than in bladder cancer is the DNA mismatch repair gene *MSH2* (Leach et al, 2000).

Specific Procedures

Bilateral disease, either synchronous or metachronous, is seen in 1% to 4% of patients (Petkovic, 1975; Babaian and Johnson, 1980; Murphy et al, 1981), and thus imaging of the contralateral kidney is required on a regular basis. Yearly CT urography is usually sufficient and also can serve for metastatic surveillance, having replaced intravenous urography. However, retrograde pyelography may be necessary if the patient is not a candidate for injection of iodinated contrast medium or if the urographic phase is not diagnostic. Magnetic resonance urography is another option for those unable to receive iodinated contrast, but patients with a creatinine clearance below 30 mg/dL may not receive gadolinium contrast because of concerns with development of nephrogenic systemic fibrosis. CT or ultrasonography is helpful in distinguishing stones from soft tissue densities. Further evaluation of filling defects on imaging studies usually requires ureteroscopic evaluation.

If an organ-sparing approach is chosen, the ipsilateral urinary tract must be assessed as well as the remainder of the urinary tract. The frequency and duration of the follow-up assessments depend largely on the grade and stage of the lesion, but they are usually every 6 months for several years and annually thereafter. Radiographic evaluation of the upper tracts alone is not adequate because [Keeley and colleagues \(1997a\)](#) showed that 75% of early tumor recurrences were visible endoscopically and not radiographically. With tumors approached in a percutaneous fashion, early follow-up nephroscopy can be performed through the established nephrostomy tract.

In the past, the burden of repeated endoscopic evaluation of the upper urinary tracts was a major deterrent to conservative therapy. The use of smaller, 7.5-Fr flexible ureteroscopes has greatly eased the burden of follow-up because ureteroscopes can be reliably passed up the ureter without the need for dilation of the ureteral orifice or prior stenting. Others have advocated resection of the ureteral orifice to facilitate subsequent surveillance ureteroscopy in the office setting ([Kerbl and Clayman, 1993](#)). Even though technology has somewhat facilitated follow-up, both physician and patient must be committed to nephron-sparing treatment.

Metastatic Restaging

Metastatic restaging is required in all patients at significant risk for disease progression to local or distant sites. This group includes those with high-grade or high-stage (>pT1) disease. Metastatic restaging is usually not necessary for low-grade disease when the risks of invasive and subsequent metastatic disease are negligible. Included in metastatic restaging is imaging of the ipsilateral renal bed for recurrence with cross-sectional imaging. Follow-up restaging includes chest radiography, liver function tests, cross-sectional body imaging, and selective use of bone scintigraphy based on an understanding of natural disease history and metastatic pathways ([Korman et al, 1996](#)). Follow-up of the upper tracts should be lifelong owing to a lifetime risk of development of upper tract tumors in patients with prior bladder cancer ([Herr et al, 1996](#)).

Epidemiology, Etiology, and Pathogenesis

Classification and Pathology

Staging of Retroperitoneal Sarcomas

Clinical Presentation and Workup

Treatment

Conclusions

PPrimary retroperitoneal tumors (RPTs) refer to a group of rare neoplasms arising in the retroperitoneum and pelvis. Although RPTs do not necessarily arise from the urogenital tract, urologists are often involved in their diagnosis and management. Furthermore, because the urinary tract is located in the retroperitoneum and pelvis, it often becomes involved with a growing RPT, necessitating proficiency in complex reconstructive urology with the goal of organ and function preservation, or occasionally organ resection.

As a group, RPTs share some important biologic features that distinguish them from most other solid tumors. Unlike most carcinomas whose clinical manifestation, evolution, and sites of metastasis are variable depending on the organ of origin, retroperitoneal sarcomas share many common clinical features that are less influenced by tumor tissue of origin. Such features include a tendency for extensive growth before becoming clinically evident; a propensity for hematogenous dissemination typically to the lungs and liver, rather than metastasis via lymphatic pathways; and local invasion of adjacent organs. Furthermore, in most cases these tumors do not originate in a specific organ but rather grow from connective tissues normally present in the retroperitoneum and pelvis. Occasionally, heterotopic tumors occur where the tumors resemble tissues not expected within a specific anatomic area. Examples for the former tumors include liposarcoma, leiomyosarcoma, and angiosarcoma, whereas examples for the latter lesions include synovial sarcoma and osteogenic sarcoma.

RPTs represent a heterogeneous group of neoplasms comprising a majority of malignant mesenchymal cancers and a minority of benign lesions. Retroperitoneal sarcomas represent a minority of all mesenchymal cancers, most of which affect the extremities, head and neck area, and genitalia (Jemal et al, 2009).

Despite similar histologic features, retroperitoneal sarcomas may follow a more aggressive clinical course compared with their extremity counterparts. Because extremity sarcomas are more common than retroperitoneal sarcomas, much of the treatment principles germane to these tumors were gleaned from experience with extremity sarcomas; however, many differences exist with respect to the means of diagnosis, the extent of surgery, and the role of radiotherapy.

KEY POINTS: INTRODUCTION

- RPTs are a heterogeneous group of tumors.
- Malignant mesenchymal tumors are the most common type of RPTs.

EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS

As a group RPTs represent a combination of sarcomas and other benign and malignant lesions, and as the result the true incidence

of RPTs is unknown. However, **sarcomas are the most prevalent entity in this group.** It is estimated that in 2013 there were 12,020 cases of soft tissue sarcomas within the United States, with 4740 cancer-specific deaths among both adults and children (Siegel et al, 2014). Soft tissue sarcomas constitute roughly 1% and 15% of all adult and pediatric neoplasms, respectively. One of the many challenges imparted in the management of sarcomas pertains to the fact that there are over 50 different histologic subtypes, resulting in a highly heterogeneous cohort of tumors encompassed within this tumor type designation. The anatomic site of origin of sarcomas is an important consideration in the management and expected treatment outcome of such tumors. It is reported that 60% of sarcomas originate from the extremities, 20% from the trunk, 15% from the retroperitoneum, and 5% to 10% from the head and neck (Pisters et al, 2011). The prognosis of retroperitoneal sarcomas is generally poor (Cormier and Pollock, et al, 2004). This is probably due to their location deep in the retroperitoneal cavity, where lesions do not readily lend themselves to detection by physical examination and the potential space of the abdomen allows for their growth to a considerable size and advanced stage before becoming clinically apparent (Paryani et al, 2012). In fact, over 50% of tumors exceed 15 cm in diameter at the time of diagnosis and tumors weighing more than 30 kg have been reported (Lehnert et al, 2009). Combined, liposarcoma, leiomyosarcoma, and malignant fibrous histiocytoma account for 80% of all retroperitoneal sarcomas (Rajiah et al, 2011). Although retroperitoneal sarcomas can occur in any age group, most are found in the sixth decade of life and men are affected slightly more often than women. Two thirds of the patients are diagnosed with high-grade disease and 10% with metastasis, mainly to the lungs and liver (Lewis et al, 1998). No specific causative factor has been identified for soft tissue sarcomas; however, radiation exposure has been implicated in the development of sarcoma within the radiated field in approximately 0.1% of the patients, typically 10 or more years after radiation exposure. The most characteristic postradiation sarcoma is malignant fibrous histiocytoma. Other risk factors include genetic predisposition; exposure to certain carcinogens, particularly dioxin; viral infection; and immunodeficiency. Occasionally, sarcoma may grow within a scar or site of previous injury and inflammation. Although sarcomatous transformation of a neurofibroma into a neurofibrosarcoma has been described, benign mesenchymal tumors almost never transform into malignant counterparts, such as lipoma transforming into liposarcoma or hemangioma developing into hemangiosarcoma. Several hereditary syndromes and congenital conditions have been associated with the development of soft tissue tumors. Research on family members affected by these syndromes has led to the identification of specific gene aberrations found in some of the sarcomas. Gardner syndrome consists of colon polyposis and mesenchymal tumors, including osteomas, lipomas, and epidermal cysts. Low-grade fibrosarcoma has been associated with this syndrome, and mutations on locus 21 to 23 on chromosome 5 have

been reported. Familial retinoblastoma has been associated with osteogenic sarcoma; and deletions in the retinoblastoma (Rb) gene have been associated with leiomyosarcoma. Other hamartomatous syndromes associated with increased soft tissue sarcoma risk include neurofibromatosis, tuberous sclerosis, von Hippel-Lindau syndrome, and Peutz-Jeghers syndrome.

The origin of soft tissue sarcomas is believed to be dormant mesodermal embryonic stem cells residing within normal adult connective tissues. These cells might be affected by exogenous stimuli such as radiation exposure, inflammation, or genetic aberration induced by carcinogens or viruses, thereby initiating the process of tumor development and progression. Several observations support the stem cell origin, as discussed in the following text.

The vast majority of soft tissue sarcomas arise de novo, and malignant transformation in preexisting benign lesions rarely has been reported. Whereas carcinomas often occur from epithelial linings with rapid cellular turnover, adult mesenchymal tissues have a much slower cellular recycling process and some are devoid of it entirely; thus genetic aberrations acquired by a mature mesenchymal cell that has low or no proliferative capability may render the defective cell prone to apoptosis and less likely to evolve into cancer. In addition, the high variability of sarcoma types, including the presence of heterotopic tissues such as synovial or osteogenic sarcomas in sites that are devoid of bone or synovium, alludes to a process of tumorigenesis from a pluripotent progenitor cell—the mesenchymal stem cell.

KEY POINTS: EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS

- Retroperitoneal sarcomas are the most prevalent primary RPTs.
- Of retroperitoneal sarcomas, 80% consist of the combination of liposarcomas, leiomyosarcomas, and malignant fibrous histiocytomas.
- Benign mesenchymal tumors almost never transform into malignant counterparts.

CLASSIFICATION AND PATHOLOGY

Benign Lesions

Benign RPTs are much less common than retroperitoneal sarcomas. The more frequent of these are lipoma, myelolipoma, leiomyoma, schwannoma, extra-adrenal pheochromocytoma, paraganglioma, and cystadenoma. **Although subcutaneous lipoma is the most common benign mesenchymal tumor, benign retroperitoneal lipoma is very rare.** Similarly, uterine leiomyoma is very prevalent in adult women. Less frequently, leiomyomas have been reported in other organs, including the kidney, prostate, ureter, bladder, spermatic cord, and penis. However, retroperitoneal leiomyoma is very rare. These are relatively small tumors, and when larger than 6 cm in diameter they are considered malignant. On light microscopy, spindle-shaped cells with cytoplasmic vacuole and central nuclei are typically present, although areas with clear cells may also be present.

Although the distinction of benign lesions from malignant tumors is difficult, some features are more characteristic of benign lesions. Most benign RPTs are small, well-circumscribed lesions and are found incidentally in asymptomatic patients. Conversely, most malignant RPTs are large and may occasionally reach enormous size; they often have poorly defined boundaries and are frequently associated with symptoms, most of which are attributed to compression of nearby organs or inanition. In addition, calcifications in retroperitoneal lesions are more characteristic of malignancy and they are rarely found in benign tumors. Although accurate histologic diagnosis is not possible based on imaging studies, some lesions have a typical appearance that can help predict their

presence. In a multivariate analysis that included 194 patients with RPTs, the following features were independently associated with the presence of a malignancy: ill-defined margins, irregular surfaces, long diameter greater than 6.75 cm, short diameter greater than 6.25 cm, solid or mixed texture, and a sensitivity and specificity of 77% and 81%, respectively (Zheng et al, 2014).

Benign retroperitoneal lipomas are typically homogenous, hypodense well-circumscribed or encapsulated lesions; however, distinction from low-grade liposarcoma, angiomyolipoma, or myelolipoma may be difficult. Microscopic examination reveals homogenous large cells with fat-laden cytoplasm leading to a flat eccentric nucleus. Excessive blood vessels or collagen may be found in variants termed as angioliipomas or fibrolipomas, respectively. Benign hibernoma (tumor of brown fat) has been reported mainly in adults. The tumor consists of large lobulated cells with cytoplasmic fat granules that stain positively with Sudan dyes. The pattern of vascular supply of these tumors is similar to that observed in the organs of hibernating mammals.

Schwannomas, ganglioneuromas, and paragangliomas are benign myxoid tumors often located in the paravertebral area. They may be oval, small, well-circumscribed masses but occasionally may be large. Anterior displacement of the pancreas or great vessels is typical. Whereas schwannomas are benign tumors arising from nerve sheath supporting cells typically with no associated symptoms, paragangliomas are composed of adrenergic nerve cells and are capable of releasing norepinephrine, provoking a syndrome akin to a pheochromocytoma, functionally producing catecholamines.

Malignant Lesions

Besides primary retroperitoneal sarcomas, other systemic cancers may manifest with retroperitoneal masses and need consideration in the differential diagnosis. Retroperitoneal lymphoma may manifest with retroperitoneal diffuse lymph node enlargement. Occasionally the involved lymph nodes will coalesce to form irregular masses that are indistinguishable from other primary RPTs. Lymphoma may even mimic retroperitoneal fibrosis with a homogenous dense midline mass that resembles fibrosis. **Metastatic germ cell tumors may lead to retroperitoneal lymphadenopathy that may be bulky.** Typically such masses deflect the ureters laterally, but may occur in between or anterior to the great vessels. The diagnosis of germ cell tumor can be established easily by finding a testicular mass and elevated relevant serum markers. Lymphoma may be associated with splenomegaly, elevated lactate dehydrogenase, and other symptoms.

Primary mesenchymal tumors can be classified according to the mesenchymal tissue component of origin. The primitive mesenchyme in the embryo gives rise to the development of primitive connective tissue, including adipose, fibrous, synovial, and osseous/cartilage tissues; angioblastic tissues, including blood vessels and lymphatics; and muscle tissue, including smooth or striated muscles. Table 59-1 depicts the classification of benign and malignant mesenchymal tumors according to the mesenchymal tissue of origin.

Liposarcoma is by far the most common type of retroperitoneal sarcoma. Several classifications of these have been proposed. Enzinger and Winslow (1962) modified a previous classification by Stout and proposed five categories: (1) myxoid, (2) well-differentiated, (3) round cell, (4) de-differentiated, and (5) pleomorphic. The first two are considered low-grade and the last three high-grade sarcomas. **Myxoid liposarcomas** are composed of primitive lipoblasts that do not have the typical fat-laden cytoplasm but rather resemble primitive mesenchymal cells. Abundant capillary network and myxoid matrix are other typical components. The histologic appearance of **well-differentiated liposarcoma** closely resembles that of a benign lipoma, and the distinction between the two by imaging and even under the microscope is a challenge. In fact, many well-differentiated liposarcomas are misdiagnosed as deeply seated lipomas. In a recent study, experienced magnetic resonance imaging (MRI) radiologists who were blinded

TABLE 59-1 Classification of Mesenchymal Tumors

TISSUE OF ORIGIN	BENIGN TUMOR	MALIGNANT TUMOR
Adipose	Lipoma Angiolipoma/angiomyolipoma Lipoblastoma Hibernoma Lipomatosis	Well-differentiated liposarcoma De-differentiated liposarcoma Myxoid liposarcoma Round cell (poorly differentiated) Pleomorphic type
Fibrous	Fibroma Angiofibroma Myositis ossificans Elastofibroma Aggressive fibromatosis	Fibrosarcoma
Fibrous histiocytic	Fibrous histiocytoma Juvenile xanthogranuloma Xanthoma Others	Malignant fibrous histiocytoma Storiform, myxoid, giant cell, xanthomatous variants
Muscle tissue Smooth muscle Striated muscle	Leiomyoma Epithelioid leiomyoma Angiomyoma Leiomyomatosis Rhabdomyoma	Leiomyosarcoma Epithelioid leiomyosarcoma Rhabdomyosarcoma
Neural tissue Sympathochromaffin tumors	Schwannoma Neurofibroma Neurofibromatosis Ganglioneuroma Pheochromocytoma	Malignant schwannoma Malignant peripheral nerve sheath tumor Malignant granular cell tumor Malignant melanoma Neuroepithelioma Ewing sarcoma Ganglioneuroblastoma Neuroblastoma Malignant pheochromocytoma
Synovial tissue	Synovioma Giant cell tumors of the tendon sheath	Synovial sarcoma
Vascular tissue	Hemangioma	Angiosarcoma Kaposi sarcoma
Lymphatic tissue	Lymphangioma	Lymphangiosarcoma

to the histologic diagnosis failed to distinguish lipomas from well-differentiated liposarcomas in 30% of the cases. Distinction criteria included nodularity, stranding, and tumor borders (O'Donnell et al, 2013). Although well-differentiated liposarcomas seldom metastasize, local recurrence is common and long-term prognosis is influenced by the morbidity caused by such recurrences involving other organs and the morbidity of the necessary surgeries.

Round cell liposarcoma is composed of small round cells uniform in size and closely packed together. There is no specific pattern of cellular arrangement and intracellular lipid content is scarce. **De-differentiated liposarcoma** is characterized by the coexistence of well-differentiated and poorly differentiated areas within the same tumor. Occasionally, at the time of local recurrence other phenotypes may be present, including malignant fibrous histiocytoma, rhabdomyosarcoma, or leiomyosarcoma.

Characteristic features of **pleomorphic liposarcoma** include a disorderly growth pattern with cellular pleomorphism, giant cells, and anaplastic pyknotic nuclei. Because this anaplastic tumor resembles other undifferentiated sarcomas, some lipoblastic presence must be documented to confirm this diagnosis. All lipocytes and lipoblasts stain positive with the immunostaining agent S-100, rendering this a useful tool in establishing this diagnosis. Genetic aberrations, including a balanced translocation of chromosomes 12 and 16 t(12:16) (q13:p11), appear in 90% of myxoid liposarcoma cases and are pathognomonic of this sarcoma (Eneroth et al,

1990). Ring chromosome 12 is typical of well-differentiated liposarcomas but also has been demonstrated in benign lipomas (Dal Cin et al, 1993).

Malignant fibrous histiocytoma has been the subject of controversy from both an ontogenetic and diagnostic standpoint. Although its name implies that histiocytes are the building block and cell of origin, truly this is a fibroblast neoplasm. Microscopic findings include round histiocyte-like cells, spindle-shaped fibroblasts, foamy cells, giant cells, and lymphocytes. Several subtypes have been reported; whereas the myxoid subtype is associated with a somewhat more favorable prognosis, the other subtypes are aggressive and show a high tendency to metastasize. In addition, some studies have shown an association between the presence of lymphoproliferative disorders, including leukemia, and both Hodgkin and non-Hodgkin lymphoma, and the development of malignant fibrous histiocytoma. The cause of this apparent relationship between malignant fibrous histiocytoma and hematologic malignancies remains unclear.

Retroperitoneal leiomyosarcomas usually occur in women in their 7th decade. The tumors attain very large size and include cystic degeneration and necrosis. Microscopic findings include spindle-shaped cells with abundant cytoplasm and cigar-shaped nuclei. As is the case with well-differentiated liposarcoma, distinction of a leiomyoma from a leiomyosarcoma is difficult even under rigorous microscopic review. Parameters suggestive of malignancy include

tumor size, pleomorphism, cellularity, necrosis, atypia, and mitosis. Of these, mitosis is the most highly predictive feature and in RPTs 1 mitosis per 10 high-power fields (HPFs) is characteristic of malignancy, whereas more mitotic figures are tolerated in smooth muscle tumors in other anatomic locations. Tumor grade is an important prognostic factor because high-grade tumors are associated with a less favorable outcome.

KEY POINTS: CLASSIFICATION AND PATHOLOGY

- Benign retroperitoneal lipomas are very rare as opposed to subcutaneous benign lipomas, which are the most common type of benign mesenchymal tumor.
- In addition to primary retroperitoneal sarcomas, other systemic malignancies such as retroperitoneal lymphoma and metastatic germ cell tumors may manifest as retroperitoneal masses and need consideration in the differential diagnosis.
- Retroperitoneal liposarcoma is by far the most common type of retroperitoneal sarcoma.

STAGING OF RETROPERITONEAL SARCOMAS

Hematogenous spread is the principal route of metastasis for sarcomas, and the lungs are the most common metastatic site for such tumors, followed by the liver. Because cross-sectional imaging is necessary as the initial diagnostic workup, liver involvement will be picked up in the initial imaging procedure. Chest computed tomography (CT) is required for all retroperitoneal sarcomas to detect pulmonary metastasis. Other sites such as bones and brain are infrequently involved, and routine imaging of these sites using brain MRI and bone scintigraphy is not required in the absence of relevant symptoms. The exceptions may be lymphangiosarcoma, osteogenic sarcoma, and Ewing sarcoma—all of which also may involve the skeleton, and bone scans should be obtained in such patients.

The tumor, node, metastasis (TNM) staging system has been used to define the local and systemic extent of tumors as follows:

T0	No demonstrable tumor
T1	Tumor measuring <5 cm in maximal diameter
T2	Tumor measuring ≥5 cm in maximal diameter
T3	Evidence of macroscopic invasion of nearby structures by the tumor
N0	No histologic evidence of regional lymph node involvement
N1	Histologically proved regional lymph node involvement
M0	No distant metastasis
M1	Distant metastasis present

In addition, the extent of surgical resection of the primary tumor is also reported, because this has been shown to portend prognostic implication, as follows:

R0	Tumor was entirely resected with no residual tumor and negative surgical margins
R1	Microscopic residual tumor = positive surgical margins
R2	Macroscopic residual tumor
R3	Tumor spillage and dissemination during resection

With regard to retroperitoneal sarcomas, in most cases tumor stage is T2 or more; the extent of other structure invasion plays a minor prognostic role as long as the tumor may be completely resected; and lymphatic involvement is rare.

Besides this staging system, several histologic parameters have been shown to affect prognosis. Tumor grade is the most

important of those; it is determined by taking into account tumor cellularity, pleomorphism, necrosis, anaplasia, and mitosis. Of these, the mitotic index (number of mitoses per 10 HPFs) and necrosis are independent prognostic factors whose impact is variable depending on tumor type (El-Jabbour et al, 1990; Hashimoto et al, 1992; Catton et al, 1994). In addition, molecular markers, including ploidy, chromosomal aberrations, proliferative index, and tumor promoter and suppressor gene mutations have been shown to influence outcome.

KEY POINTS: STAGING OF RETROPERITONEAL SARCOMAS

- The most common site of metastatic progression of retroperitoneal soft tissue sarcomas is the lungs, followed by the liver.
- In addition to TNM clinical staging, other prognostic factors for retroperitoneal sarcomas include tumor grade, mitotic index, necrosis, and molecular markers.

CLINICAL PRESENTATION AND WORKUP

Before histologic diagnosis of an RPT is available, its presence is typically heralded by imaging findings either as part of a workup for a suggestive clinical presentation or as an incidental finding on an imaging procedure undertaken for other unrelated reasons. At present, cross-sectional imaging by CT or MRI provides accurate data on tumor size, location, relations to nearby structures, and other features, including heterogeneity, boundaries, vasculature, necrosis, and calcification. CT depicts a solid (>15 Hounsfield units) texture to the suspect lesions, but may demonstrate necrosis, calcifications, and anatomic relations to nearby blood vessels and organs. Adipose tissue tumors may show the typical hypodense attenuation; however, the distinction of various types of benign and malignant fat-containing tumors is not possible by CT. The presence of dense areas within a fatty tumor may allude to de-differentiated liposarcoma. Most RPTs have long T₁ and T₂ relaxation times and appear hypointense on T₁-weighted images and hyperintense on T₂-weighted images. MRI has been very sensitive in demonstrating fat-containing tumors. The role of positron emission tomography (PET-CT) for initial diagnosis and staging is less well established, and probably it is most useful to delineate retroperitoneal lymphoma, which is PET positive in many cases, and distinguish it from other tumors. In contrast, several reports found correlation between fluorodeoxyglucose (FDG) avidity and grade of liposarcoma, although FDG avidity of other sarcomas is less predictable and often absent (Kitajima et al, 2013). In the postsurgery follow-up phase there may be a role for PET-CT, because it showed superior specificity compared with contrast-enhanced CT for well-differentiated liposarcoma, lymph node metastasis, and pulmonary metastasis. The specificity of PET-CT remained poor for leiomyosarcoma and liver metastasis (Niccoli-Asabella et al, 2013). At the present time, the role of PET-CT in the management of RPTs remains unclear.

Due to their location deep in the retroperitoneum, which is not a confined space, many RPTs can grow to a vast size before prompting the patient's attention. Thus very large tumors (>15 cm or weighing several kilograms) may occasionally be found. In the absence of distant metastasis and local involvement of nearby organs, most tumors can remain asymptomatic for an extended duration. Eventually, however, a sensation of an abdominal mass or abdominal pain (in 80% of patients) and constitutional symptoms, such as weight loss (30% of patients), fatigue, early satiety, and inanition may ensue, as the metabolic requirements of the growing tumor deplete the host of needed resources. Neurologic symptoms also occasionally may occur. A typical complaint is of weight loss in conjunction with abdominal girth enlargement as a

result of the presence of a large abdominal tumor. Compression of nearby organs may elicit additional symptoms, including abdominal discomfort, nausea, flank or pelvic pain, and hematuria.

Physical examination may be unrevealing, or a large abdominal mass may be palpated and sometimes even be visible. Leg edema and symptoms of inferior vena cava syndrome may be found. Abdominal ultrasound is often used as a screening tool to evaluate physical findings of an abdominal mass or suspicious symptoms. However, cross-sectional imaging with CT or MRI provides a more accurate diagnosis of the primary tumor and provides local staging. Further staging with a chest CT is routine. The differential diagnosis of retroperitoneal masses includes lymphoma, retroperitoneal sarcoma, metastasis, and, rarely, benign RPTs. Nonsolid lesions such as congenital and acquired cysts, arterial aneurysms, and inflammatory lesions (i.e., psoas abscess) usually can be suspected based on previous patient history and the liquid content that is readily discerned by cross-sectional imaging.

Role of Pretreatment Biopsy

A pretreatment biopsy is important in cases in which lymphoma is suspected. Because the mainstay of lymphoma therapy is not surgery but rather systemic chemotherapy, a percutaneous imaging-guided needle biopsy may expedite the diagnosis and direct the patient toward appropriate treatment (Quinn et al, 1995). Other clinical scenarios in which a biopsy may be indispensable include patients in whom metastasis from a preexisting cancer is suspected, patients with a mass that appears surgically unresectable, or patients with a suspected sarcoma in whom metastatic disease is noted on imaging, and a biopsy may guide chemotherapy. It is also highly recommended to obtain a pretreatment biopsy sample to establish the diagnosis and grade in select patients suspected of having a surgically resectable retroperitoneal/intra-abdominal sarcoma (Von Mehren et al, 2015). It is well established within the sarcoma literature that the underlying tumor biologic status (grade) and sarcoma histologic subtype are important prognostic factors for retroperitoneal sarcomas and often both can be characterized on a diagnostic biopsy specimen, hence often enabling us to develop a personalized treatment approach to a given patient (Gronchi et al, 2004; Grobmyer et al, 2010). The pretreatment biopsy is particularly useful if the suspected soft tissue sarcoma is being considered for presurgical therapy (i.e., radiotherapy and/or systemic therapy). However, if the final common pathway is surgery, a preoperative biopsy is in fact not necessary. One such example in which preoperative imaging without a biopsy is all that is needed is in a patient with a retroperitoneal liposarcoma. If a pretreatment biopsy is felt to be beneficial, it can be performed by an interventional radiologist or surgeon using either an image (CT, MRI, or ultrasound)-guided core (14- or 16-gauge coaxial needle) or, rarely, an open/minimally invasive surgical incisional-guided technique, depending on the location of the retroperitoneal mass and amenability to a minimally invasive procedural technique. It is thought by many experts that an image-guided core biopsy is the preferred technique, avoiding the potential of cancer dissemination within the future surgical field from an open/minimally invasive surgical biopsy, which can complicate and potentially adversely affect the outcome of the subsequent definitive management. A frozen section assessment of the biopsy can at times be beneficial in ensuring that an adequate diagnostic biopsy specimen has been obtained but should not be used, for example, during surgery because it is often inaccurate for such tumors. Whenever feasible, a retroperitoneal (vs. transperitoneal) image-guided biopsy should be obtained to avoid the theoretical risk for peritoneal seeding along the needle tract. It is important to highlight at this point that although a fine-needle aspiration is a convenient way of obtaining tissue, it is often nondiagnostic and/or minimally informative in providing histopathologic details because of the small amount of tissue obtained with this technique (Domanski, 2007). At times, a biopsy guided by endoscopy (upper or lower gastrointestinal endoscopy or bronchoscopy) may be appropriate to access a thoracic, abdominal, or

pelvic situated lesions. Importantly, definitive treatment decisions often cannot be finalized until the diagnostic biopsy has been reviewed by a pathologist with expertise in soft tissue sarcomas, often necessitating the use of immunohistochemical staining and molecular testing.

KEY POINTS: CLINICAL PRESENTATION AND WORKUP

- A pretreatment biopsy is important in cases in which lymphoma is suspected. In addition, a biopsy may be indispensable in patients in whom metastasis from a preexisting cancer is suspected, patients with a mass that appears surgically unresectable, or patients with a suspected sarcoma in whom metastatic disease is noted on imaging and a biopsy may guide subsequent systemic therapy. It is also highly recommended to perform a pretreatment biopsy to establish the diagnosis and grade in select patients suspected of having a surgically resectable retroperitoneal/intra-abdominal sarcoma.
- If a pretreatment biopsy is felt to be beneficial, it can be obtained by an interventional radiologist or surgeon using either an image (CT, MRI, or ultrasound)-guided core (14- or 16-gauge coaxial needle) or, rarely, an open/minimally invasive surgical incisional-guided technique depending on the location of the retroperitoneal mass and amenability to a minimally invasive approach.

TREATMENT

Principles of Sarcoma Surgery

Definitive surgical resection remains the standard primary treatment of retroperitoneal sarcomas; however, if it is deemed a tumor cannot be surgically resected while ensuring negative surgical margins, preoperative (neoadjuvant) radiotherapy and/or systemic therapy should be considered, with such cases best managed by a multidisciplinary team (medical and surgical oncology as well as input from radiation oncology). In retroperitoneal sarcomas deemed resectable with anticipated negative final surgical margins, it cannot be emphasized enough that the quality and adequacy of the surgical resection is imperative in determining the likelihood of potential cure (Bonvalot et al, 2012). Unlike primary tumors of epithelial origin, which are typically contained within a single organ site and therefore can be surgically eradicated by the resection of that specific organ, retroperitoneal sarcomas typically extend, with direct contact to a number of abdominal/retroperitoneal structures without necessarily invading them based on preoperative imaging. In consequence, **local control remains a significant problem and furthermore is the leading cause of death, particularly for the low- to intermediate-grade tumors**, which are estimated to constitute approximately 75% of all retroperitoneal sarcomas.

Earlier retroperitoneal sarcoma surgical series had reported disappointing local recurrence-free survival (RFS) rates of 50% at 5 years (Lewis et al, 1998); however, more recent surgical series have reported significantly improved RFS rates of up to 75% to 80% at 5 years (Bonvalot et al, 2010; Gronchi et al, 2012), as shown in Table 59-2. The better surgical outcomes reported in recent years can be attributed in large part to a more aggressive approach in which all concerning organs suspected to be involved are resected en bloc with the specimen whenever feasible. This minimizes the risk for microscopically positive surgical margins. It is evident that a fine line exists between the resection of organs potentially grossly or microscopically involved with a retroperitoneal soft tissue sarcoma and the resection of important vital organs for which there is questionable involvement and potential exponentially increasing morbidity and/or mortality of the resection. It must be emphasized, however, as nicely depicted in an editorial, that the liberal resection

TABLE 59-2 Historical Series on Surgical Outcomes of Retroperitoneal Sarcoma Resection

SURGICAL SERIES	STUDY PERIOD	STUDY POPULATION	COMPLETE RESECTION (%)	OVERALL SURVIVAL (% AT 5 YR)	LOCAL RFS (% AT 5 YR)	MEDIAN FOLLOW-UP (MO)
Lewis et al (1998)	1982-1997	231	80	54	59	28

NR, not reported; RFS, recurrence-free survival.

of adjacent uninvolved viscera may allow a subset of patients to more consistently achieve microscopically negative resection margins, but it remains unclear whether this additional resection translates into an improvement in cancer-specific survival (Pisters, 2009). It is reasonable to recommend in patients with low-grade soft tissue retroperitoneal sarcomas that they undergo such a surgical approach because such tumors have such a low metastatic potential. It can be argued, however, that such patients may harbor indolent disease that can remain asymptomatic for months to years, thereby putting into question the ultimate benefit of surgical resection. Regardless, the objective of surgical resection in this clinical context is to achieve a wide microscopic negative surgical margin by removing easily disposable organs (e.g., kidney, spleen, tail/body of pancreas, psoas muscle) while performing only what is critical in terms of the resection of vital anatomic structures (e.g., aorta, inferior vena cava, iliac vessels, duodenum, head of pancreas, diaphragm, femoral nerve). When true extension into major vascular structures is anticipated, expertise in the surgical management of vascular resection, with the potential use of vascular bypass or grafting, should be readily available and the potential necessity for major intraoperative transfusions should be anticipated and discussed with the patient and anesthesia team preoperatively. In some cases, it is feasible to dissect major vessels under the adventitia, bone under the periosteum, and nerves under the epineurium as a means to obtain negative microscopic margins (Kawaguchi et al, 2004; Lin et al, 2007). However, if the adventitia of these respective organs is invaded, these should be resected if deemed technically feasible, taking the patient's performance status, comorbidities, and estimated prognosis into account. Surgeons embarking on such procedures must determine which anatomic sites must be resected to ensure negative microscopic surgical margins are obtained and balance this in the context of optimizing the patient's quality of life and minimizing the morbidity of the surgical procedure. Such decisions and considerations taken by the surgeon must take into account the patient's individual expectations and goals as well as whether this is a primary versus recurrent retroperitoneal sarcoma. Clearly, all of these nuances of the surgical management of a retroperitoneal sarcoma must be discussed with the patient preoperatively and counseled accordingly.

A very meticulous review of preoperative imaging by the surgeon and his team is imperative before embarking on retroperitoneal sarcoma surgical resection. A CT scan with intravenous contrast of the abdomen and pelvis is the most frequently used diagnostic imaging modality. CT imaging is excellent in diagnosing a suspected retroperitoneal liposarcoma, with typically well-differentiated fat usually indicative of a low-grade liposarcoma, although renal angiomyolipomas and adrenal myelolipomas remain in the differential diagnosis and must be considered. To distinguish these from one another, it must be remembered that angiomyolipomas frequently have smooth muscle and large vascular structures within the fatty component of the mass whereas adrenal myelolipomas are solely fat-containing tumors that originate from within the anatomic boundaries of the adrenal gland. **A principle to adopt**

is that any large lipomatous tumor originating from the retroperitoneal space be considered a well-differentiated retroperitoneal liposarcoma until proved otherwise. Importantly, if a fat-containing tumor has one or more areas of increased density, the diagnosis of a retroperitoneal liposarcoma is more significantly suspected. It can be challenging to determine if these areas of greater density in fact represent de-differentiated components of the tumor versus potential well-differentiated liposarcomatous histologic subtypes such as inflammatory, myxoid-like, or sclerosing lesions (Lahat et al, 2009). If the surgeon feels this determination may influence his treatment decision in terms of proceeding with surgical resection versus consideration of neoadjuvant radiotherapy and/or systemic therapy, a diagnostic percutaneous biopsy sample can be obtained. At this point, it is important to highlight a common mistake made by treating physicians/surgeons not intricately familiar with the radiographic appearance of retroperitoneal liposarcomas, which is to focus on the high-density component of the lipomatous tumor and assume the rest of the fat is normal, which consequently may be left behind at the time of the surgical resection at some centers not exhibiting such surgical expertise/experience. **In retroperitoneal masses exhibiting higher density without a fatty component on CT imaging (with intravenous contrast), a percutaneous biopsy should be considered absolutely necessary to differentiate a soft tissue retroperitoneal sarcoma from other tumor types, such as a germ cell neoplasm (in males), lymphoma, or a desmoid tumor. It should be considered absolutely imperative to perform a bilateral testicular physical examination in any male patient presenting with an RPT, with a bilateral testicular ultrasound with Doppler performed in any male patients with a concerning testicular examination for a solid intraparenchymal testicular mass, with the use of testicular cancer serum tumor markers (α -fetoprotein, β -human chorionic gonadotropin, and lactate dehydrogenase) encouraged as well.**

Although many surgical approaches can be employed in tackling what often can be large retroperitoneal liposarcomas, the most common incisions are typically a midline or subcostal/chevron approach. Both incision types allow for excellent exposure to abdominal/pelvic organs, which can be reflected superiorly to allow access to retroperitoneal organs and major vascular structures (van Vreeland et al, 1995). For large RPTs situated in the right upper quadrant, some surgeons prefer a thoracoabdominal incision allowing great visibility and enabling extensive mobilization of the liver, with great exposure of the intrathoracic and intra-abdominal components of the inferior vena cava as well as the right kidney and adrenal gland. Before initiating the surgical resection, it is sometimes deemed beneficial to cystoscopically place a temporary open-end ureteral stent(s) in that large retroperitoneal sarcomas often can intimately involve various segments of the ureter; hence the placement of such stents can serve as a reference point to the precise intraoperative location of the ureter(s) in their entirety, thereby potentially obviating the risk for any intraoperative ureteral injuries and need for ureteral reconstruction.

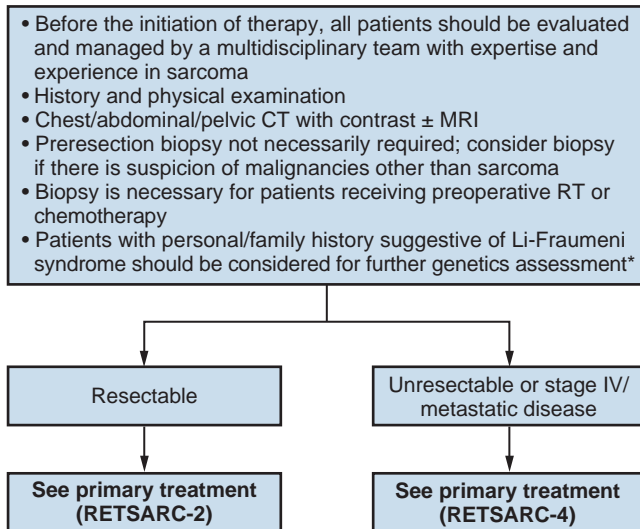

Evidence-Based Treatment Guidelines

The pivotal therapeutic consideration in the management of retroperitoneal/intra-abdominal sarcomas pertains to a determination of whether it is felt the retroperitoneal sarcoma is resectable versus unresectable (or stage IV), as shown in [Figure 59-1](#) ([Von Mehren et al, 2015](#)). This determination should be made by a multidisciplinary team with expertise in the management of sarcomas after careful review of the case using CT imaging with intravenous contrast (\pm MRI) of the chest, abdomen, and pelvis. As discussed in the prior section, a biopsy of the mass (percutaneous core needle biopsy preferably) can be helpful in confirming the histologic diagnosis of a sarcoma and/or determining if neoadjuvant radiotherapy and/or systemic chemotherapy would be beneficial for large (typically > 4 cm) or de-differentiated tumors. In this context for surgically managed retroperitoneal sarcomas in which microscopic or grossly positive margins are anticipated based on intraoperative surgical findings, surgical clips should be applied in these areas to mark the site(s) at increased risk for local recurrence. Although adjuvant radiotherapy is not generally advocated for low-grade retroperitoneal/intra-abdominal soft tissue sarcomas, some have advocated postoperative adjuvant radiotherapy for intermediate- to high-grade tumors, but it is widely believed that such therapy has a limited role because the required radiation dose for local cancer control in the adjuvant setting exceeds that tolerable by the bowel. In this regard, most experts believe adjuvant radiotherapy should be reserved to imperative indications such as grossly positive surgical margins after surgical resection in patients not amenable to repeat resection with negative gross and final

surgical margins. As discussed in earlier sections, it is imperative for surgeons conducting retroperitoneal sarcoma surgery to strictly adhere to the principle of surgical resection with negative margins with the removal of all involved organs. Surgical margins should be documented by both the surgeon and pathologist in evaluating the status of the resection margins. If a surgical margin is deemed positive on final pathologic review, surgical repeat resection should be strongly considered provided this is not deemed either excessively morbid and/or adversely affecting the subsequent quality of life these patients would be rendered ([Von Mehren et al, 2015](#)).

In retroperitoneal/intra-abdominal sarcomas deemed unresectable (or stage IV), a biopsy (preferably percutaneous image guided) to establish the diagnosis should be considered to help confirm first the diagnosis of a soft tissue sarcoma as well as the grade and histopathologic features of the underlying tumor, because these may help dictate which systemic therapies may be best suited for such patients, as shown in [Figure 59-2](#). The role of a multidisciplinary team with expertise in the management of soft tissue sarcomas is imperative in such cases, because patients often will benefit from both local (surgery or radiotherapy) and systemic therapy, as shown in the National Comprehensive Cancer Network® (NCCN®) treatment algorithm. In patients with unresectable (or stage IV) retroperitoneal/intra-abdominal sarcomas being treated with a combination of radiotherapy and systemic therapy, external beam radiotherapy typically is employed in an attempt to obtain local control, often concomitantly with systemic therapy (i.e., chemotherapy and/or small molecule targeted therapy). If the tumor is deemed to have a favorable response with downstaging such that it becomes resectable, subsequent consolidative surgery is recommended. Patients with unresectable (or stage IV) retroperitoneal/intra-abdominal sarcomas exhibiting either no evidence of downstaging after systemic therapy (\pm radiotherapy) or deemed unresectable at time of attempted consolidative surgery, should be treated with palliative therapeutic options (radiotherapy, chemotherapy, surgery), with the end point of such therapy being symptomatic control. Additional therapeutic options for such patients include resection of metastatic sites of disease if the primary tumor can be controlled as well as observation if they remain asymptomatic. If these patients are symptomatic, it is reasonable to consider a palliative surgical resection, which can provide some degree of (short-term) local cancer control with a resulting improved quality of life. Clinical trial participation should be considered for such patients, with best supportive care measures being initiated in patients with symptomatic disease progression. In this regard, it is important to highlight that observation itself is a suitable option in asymptomatic patients because it optimizes the quality of life of these patients in the context of their adverse prognosis. Similarly, in some select reports, incomplete surgical resection of retroperitoneal liposarcomas has in fact been shown to improve survival in addition to successful symptom palliation ([Shibata et al, 2001](#)). Supportive measures should be initiated early in such patients because the likelihood of rapid cancer progression and symptomatology is exceedingly high over the subsequent weeks.

Role of Perioperative Radiotherapy

Radiotherapy is an integral therapeutic tool in the management of retroperitoneal soft tissue sarcomas, with its potential role as a primary treatment modality or as part of a multimodal treatment in which it is typically delivered in the neoadjuvant (preoperative) or adjuvant (postoperative) setting. A number of pioneering studies have supported the important therapeutic role of radiotherapy in the management of soft tissue retroperitoneal sarcomas ([Suit and Russell, 1975](#); [Tepper et al, 1984](#)). Significant technologic milestones have been reached in the delivery of radiotherapy with brachytherapy, intensity-modulated radiation therapy (IMRT), and intraoperative radiation therapy (IORT), now readily available choices and offering patients potential superior treatment outcomes ([DeLaney et al, 2005](#)). As has been shown in several long-term

‡See systemic therapy agents and regimens with activity in soft tissue sarcoma (SARC-E).

§The most active chemotherapy regimen in an unselected patient population is AIM (doxorubicin/ifosfamide/mesna) (Judson et al, 2014).

||See radiation therapy guidelines (SARC-D).

¶Resection of resectable metastatic disease should always be considered if primary tumor can be controlled.

#Palliative RT requires balancing expedient treatment with sufficient dose expected to halt the growth of or cause tumor regression. Numerous clinical issues regarding rapidity of growth, the status of systemic disease, and the use of chemotherapy must be considered. Recommended only for patients with unresectable or progressive disease.

studies, IORT in select patients with primary and recurrent retroperitoneal soft tissue sarcomas results in excellent local control and disease-free survival with limited treatment-related morbidity (Willett et al, 1991; Gieschen et al, 2001). IMRT similarly allows delivery of high doses of radiation to the primary tumor site while

minimizing radiation exposure to the surrounding tissues by contouring the external radiotherapy through highly precise treatment planning and simulation (Leibel et al, 2002). In contrast, IORT entails the application of radiotherapy during surgery, typically using a brachytherapy or electron beam radiotherapy technique.

Preoperative radiotherapy is frequently used in the management of large or poorly differentiated retroperitoneal sarcomas because, first, the treatment volume is typically a smaller field, being that the entire operative field does not need to be covered, and as well the risk for tumor seeding at time of surgical resection is reduced as a consequence of the preoperative radiotherapy. The sarcoma may or may not shrink, but the pseudocapsule surrounding the tumor often will thicken and be rendered avascular, which can facilitate the subsequent surgical resection. The main drawback to preoperative radiotherapy is that it can impair wound healing, typically with an interval of 3 to 6 weeks between the completion of radiotherapy and the definitive proceeding surgical resection, which may result in significant local effects of acute radiation delivery (inflammation, tissue edema, and poor tissue and wound vascularity). It is important to note, however, that some reports would suggest that preoperative radiotherapy followed by aggressive surgical resection, although well tolerated, did not result in a significant clinical improvement in treatment specific outcomes versus surgery alone (Ballo et al, 2007). A typical preoperative dose of radiotherapy of 50 Gy is employed, and if wide negative surgical margins are obtained at the time of resection, no further radiotherapy is often recommended, because reported local control rates of up to 95% have been reported when preoperative radiation at a treatment dose of 50 Gy is employed and negative surgical margins are obtained on the subsequent surgical resection. However, in cases in which a positive or close positive margin is demonstrated, a radiation boost delivered by external beam radiotherapy or IORT is often recommended. An IORT dose of 10 to 12.5 Gy is recommended for microscopically positive margins, and an IORT dose of 15 Gy is recommended for gross residual disease (Von Mehren et al, 2015).

Postoperative radiotherapy has been demonstrated to improve local cancer control for high-grade soft tissue sarcomas in patients with positive surgical margins (Alektiar et al, 2000; DeLaney et al, 2007). Recommendations pertaining to adjuvant radiotherapy, however, should be individualized and not entirely based on margin status at time of the original or subsequent repeat resection, as demonstrated by the exceedingly low 5-year local recurrence rate of 9% reported in a cohort of limb-affecting soft tissue sarcomas on their repeat resection exhibiting negative surgical margins with no subsequent adjuvant radiotherapy (Cahlon et al, 2008). Postoperative radiotherapy can be delivered in one of several ways, including external beam radiotherapy, brachytherapy, or IORT. It is important to emphasize that adjuvant radiotherapy should not be considered in any way as a compensation for incomplete or poorly conducted surgical resection because the primary end point of retroperitoneal sarcoma surgery should be complete resection with negative gross and microscopic surgical margins while attempting to preserve all nonaffected organs. A therapeutic principle often adhered to is that adjuvant radiotherapy would be the treatment of choice to control microscopic residual disease if repeat resection is not feasible or is refused by patients. When adjuvant radiotherapy is employed, typically the entire operative field is included within the treatment area, with the total dose delivered taking into account the maximal tolerable dose such tissues can be safely administered. Postoperative external beam radiotherapy for such tumors has frequently been conducted using IMRT technology (proton therapy has as well been used in recent years) requiring complex pretreatment planning, taking into account the extent of the surgical procedures and redistribution of organs after the prior resection. IORT can also be used in the postoperative adjuvant setting; however, it has never been shown to be superior to external beam radiotherapy, so definitive recommendations of IORT versus other adjuvant radiotherapy modalities are inconclusive at the present time (Tran et al, 2006). When administered to patients with positive surgical margins, IORT is

delivered at 10 to 16 Gy followed by consolidative external beam radiotherapy at a dose of 50 Gy (Von Mehren et al, 2015).

Role of Perioperative Systemic Therapy

The benefits imparted by neoadjuvant systemic chemotherapy followed by surgical resection have been for the most part inconsistent. In one prior study, the benefit of neoadjuvant chemotherapy was demonstrated only among patients with high-grade sarcomas larger than 10 cm (Grobmyer et al, 2004). The only reported prospective trial comparing surgery alone versus neoadjuvant chemotherapy and followed by surgical resection among patients with high-grade sarcomas was a negative study and did not validate the benefit of treating such patients with a multimodal approach (Gortzak et al, 2001). In this trial, the estimated 5-year disease-free survival was 52% and 56% for the surgery alone and neoadjuvant chemotherapy followed by surgery arms, respectively, which was a non-statistically significant difference. Similarly, the 5-year overall survival rates were 64% and 65%, respectively, for both these treatment arms.

Significantly more robust data exist to support the benefit imparted to adjuvant (i.e., postoperative) systemic chemotherapy in terms of recurrence-free survival among patients with soft tissue sarcomas, although most of these data pertain to extremity sarcomas. An Italian phase 3 trial randomized patients with high-grade primary or recurrent soft tissue sarcomas to undergo either surgical resection alone or surgery followed by systemic chemotherapy consisting of epirubicin and ifosfamide (Frustaci et al, 2001). The estimated overall survival benefit of systemic chemotherapy was 13% at 2 years and subsequently increased to 19% at 4 years. In a subsequent study at a median follow-up of 90 months, the authors reported a 5-year overall survival rate of 66% and 46%, respectively, for this combination treatment arm versus surgery alone (Frustaci et al, 2003). Unfortunately, this difference was not statistically different when the intention-to-treat analysis was conducted. Several meta-analyses have been conducted validating the benefit of adjuvant systemic chemotherapy after surgical resection for soft tissue sarcomas. In a meta-analysis of 14 randomized trials, 1568 patients with soft tissue sarcoma were treated with surgery and adjuvant chemotherapy employing doxorubicin-based regimens versus surgery alone. There was a demonstrated and statistically significant improvement in recurrence-free survival rates to the multimodal treatment area; however, there was no statistically significant improvement in overall survival, although this trended toward significance (Sarcoma Meta-analysis Collaboration, 1997). This benefit of adjuvant systemic chemotherapy was subsequently validated in another meta-analysis in which there was an improvement in local, distant, and overall recurrence-free survival in addition to an overall survival benefit with this multimodal approach (Pervaiz et al, 2008). In a recent study by the French Sarcoma Group, they corroborated the benefit of postoperative chemotherapy with a significant improvement in reported 5-year metastatic-free survival of 58% and 49% for surgery and adjuvant chemotherapy versus surgery alone for solely grade 3 soft tissue sarcomas, respectively, but this was not shown for grade 2 tumors using the Fédération Nationale des Centres de Lutte Contre le Cancer grading system (Italiano et al, 2010). A recent phase 3 study was completed by the European Organisation for Research and Treatment of Cancer (EORTC) (study 62931) in which 351 patients with macroscopically completely resected grade 2 to 3 tumors in the absence of metastatic disease were randomized to postoperative chemotherapy using ifosfamide and doxorubicin versus observation (Woll et al, 2007). The interim analysis of this study revealed no survival benefit to postoperative chemotherapy in patients with high-grade soft tissue sarcomas (the estimated 5-year recurrence-free survival was 52% in both arms). The finalized analysis of this EORTC collaborative trial is needed to further delineate the role of adjuvant systemic chemotherapy using conventional regimens after complete surgical resection of soft tissue sarcomas.

or epirubicin with either ifosfamide and/or dacarbazine) have been employed in the management of advanced or unresectable soft tissue sarcomas, as shown in Box 59-1 (Von Mehren et al, 2015). In addition, other systemic agents and/or combinations are actively being studied in present prospective trials, including gemcitabine, docetaxel, vinorelbine, pegylated doxorubicin, and temozolomide. Single-agent gemcitabine has been shown to have only moderate efficacy in the management of advanced soft tissue sarcomas (Von Burton et al, 2006), whereas combination systemic regimens employing gemcitabine and docetaxel were more potent in the management of unresectable leiomyosarcomas after disease progression after doxorubicin-based systemic therapies (Hensley et al, 2002). In subsequent studies, this combination regimen of gemcitabine and docetaxel was determined to be effective for a host of other sarcoma subtypes (Leu et al, 2004). In a phase 2 trial, a multiagent systemic regimen of gemcitabine and docetaxel was shown to offer an improvement in both progression-free (6.2 months vs. 3.0 months) and in overall survival (17.9 months vs. 11.5 months) compared to single-agent gemcitabine systemic therapy alone (Maki et al, 2007). A number of other systemic chemotherapeutic drugs, including temozolomide, pegylated liposomal doxorubicin, and vinorelbine, have some activity as single agents in the management of soft tissue sarcomas (Von Mehren et al, 2015). Trabectedin is a newer systemic agent that interferes with DNA binding and has similarly shown some promising phase 2 clinical activity in the management of advanced soft tissue sarcomas (Le Cesne et al, 2005). In addition, trabectedin is presently being investigated in an ongoing multicenter trial as a salvage agent in patients with refractory or relapsing soft tissue sarcomas after standard initial systemic therapy. The finalized data from this trial has yet to be published.

Targeted agents are a new class of drugs that have shown great promise in the management of advanced and/or unresectable soft tissue sarcomas of various subtypes. One of the best studied targeted agents as pertains to soft tissue sarcomas is the tyrosine kinase inhibitor pazopanib (Sleijfer et al, 2009). In a prior phase 3 prospective trial (EORTC 62072), a cohort of patients with metastatic soft tissue sarcoma (N = 369) having failed at least one prior course of anthracycline-based systemic chemotherapy were randomized to either pazopanib or placebo (Van Der Graaf et al, 2011). In the present study, pazopanib was shown to significantly improve progression-free survival versus placebo (20 weeks and 7 weeks, respectively), with a trend toward improved overall survival (11.9 months and 10.4 months, respectively) although this difference did not reach statistical significance. A number of other targeted agents (including imatinib, sunitinib, crizotinib, bevacizumab, and sirolimus) are actively being studied in the management of a host of advanced soft tissue sarcoma subtypes with encouraging results; however, these results remain preliminary at the present time. These systemic agents hence may be worthwhile to consider in select cases as well as always considering active ongoing clinical trials currently available to patients with relapsing or refractory disease after conventional standard first-line therapy.

Surveillance Strategies after Definitive Therapy

After definitive surgical resection, patients must be diligently followed by the multidisciplinary team because patients are at significant risk for local and distant cancer progression. The advent of postoperative predictive tools such as nomograms to estimate the likelihood of recurrence and/or survival in patients with retroperitoneal soft tissue sarcomas after surgical resection has allowed clinicians to tailor their surveillance strategy and adjuvant therapy considerations to the individualized patient (Anaya et al, 2010). The most important determinant of the likelihood of sarcoma recurrence pertains to the surgical margin status. Patients rendered R0, with no residual microscopic disease can be considered for postoperative adjuvant radiotherapy in highly selected cases, but typically such patients are not strongly recommended adjuvant radiotherapy and are followed by physical examination and imaging of the abdomen and pelvis (CT with intravenous contrast) every 3 to 6 months for up to 2 to 3 years and thereafter every 6 months for next 2 years and then annually, as shown in the NCCN treatment algorithm shown in Figure 59-3. Such patients should as well be considered for chest imaging (chest radiograph or CT chest noncontrast). In contrast, patients with

retroperitoneal/intra-abdominal sarcomas surgically resected but exhibiting microscopic residual disease (R1) should be considered for postoperative adjuvant radiotherapy, particularly if they had not received preoperative neoadjuvant radiotherapy or a boost dose (10 to 16 Gy) if neoadjuvant radiotherapy had been delivered. Such patients should similarly be followed by physical examination and imaging of the abdomen and pelvis (CT with intravenous contrast) every 3 to 6 months for up to 2 to 3 years and thereafter every 6 months for next 2 years and then annually. Chest imaging (chest radiograph or CT chest noncontrast) should be offered as well to such patients. As discussed in the prior section, patients with gross residual (R2) disease should be strongly advocated to undergo a repeat resection if deemed feasible and thereafter be carefully followed as advocated for patients with R1 disease.

KEY POINTS: TREATMENT

- Definitive surgical resection remains the standard primary treatment of most primary retroperitoneal soft tissue sarcomas deemed resectable.
- If, after multidisciplinary team review, a retroperitoneal sarcoma is deemed not surgically resected with negative surgical margins, preoperative (neoadjuvant) radiotherapy and/or systemic therapy should be considered.
- It is essential that surgeons conducting retroperitoneal sarcoma surgery strictly adhere to the principle of surgical resection with negative margins with the removal of all involved organs.
- Recommendations pertaining to adjuvant radiotherapy should be individualized and not solely based on margin status at time of the original or subsequent repeat resection.
- It is imperative to understand that adjuvant radiotherapy should not be considered a compensation for incomplete or poorly conducted surgical resection.
- Most of the data supporting the benefits imparted to adjuvant systemic chemotherapy in terms of recurrence-free survival among patients with soft tissue sarcomas pertains to extremity soft tissue sarcomas.
- The most important determinant of the likelihood of a retroperitoneal sarcoma recurrence pertains to the surgical margin status.
- Patients with retroperitoneal/intra-abdominal sarcomas surgically resected but exhibiting microscopic residual disease (R1) should be considered for postoperative adjuvant radiotherapy.

CONCLUSIONS

The management of retroperitoneal soft tissue sarcomas has evolved dramatically in recent years, with the role of preoperative imaging (and/or surgical) biopsy often being beneficial in cases in which the diagnosis is in question or in delineating the potential merit of preoperative (neoadjuvant) radiotherapy and/or chemotherapy in either poorly differentiated tumors or in those in which resectability is in question (using a systemic regimen specifically directed to that sarcoma subtype). It is imperative for surgeons embarking in retroperitoneal sarcoma surgery to understand the prognostic importance of complete surgical resection, with negative gross and microscopic surgical margins; in this regard, the extent of surgical resection may be quite extensive at times, requiring surgeons to have a wide surgical skill set in gastrointestinal, vascular, orthopedic, and reconstructive techniques. Retroperitoneal soft tissue sarcomas are rare tumor types; therefore we encourage centers and urologists caring for such patients to discuss these cases as part of multidisciplinary treatment teams such that the proper integration of suitable therapies is adopted when appropriate to optimize treatment-specific outcomes. Finally, new systemic therapy combinations and targeted agents are redefining the treatment approach to advanced soft tissue sarcomas; hence the treatment outlook for such patients is believed to be significantly more promising in the years to come.

Historical Perspective

Preoperative Evaluation and Preparation

Surgical Approaches

Surgery for Benign Diseases

Surgery for Malignancy

HISTORICAL PERSPECTIVE

Kidney-related diseases have significantly helped our understanding of the normal physiology of the kidney. As a result of better understanding of the pathophysiology and anatomic structures of the kidney, surgical approaches to management of renally related disease have evolved. From the first successful nephrectomy in 1869 for management of ureterovaginal fistula to the first radical nephrectomy, renal vasculature and caval reconstructions and advances made in retroperitoneal and transabdominal approaches for renal surgery have all stemmed from improved understanding of the surgical anatomy of the kidney and its surrounding structures. Therefore, for appropriate decision making in the perioperative period, detailed knowledge of the renal anatomy is paramount. Since renal anatomy has been discussed in detail in the anatomy chapters of this book, it will not be repeated here and the reader is referred to those chapters for review and understanding of the important surgical anatomic landmarks necessary for renal surgery.

PREOPERATIVE EVALUATION AND PREPARATION

Prior to any renal surgery, a global assessment of the patient's renal function is important. Routinely, preoperative urinalysis, urine culture, and serum creatinine (SCr) and hemoglobin should be evaluated. Patients with locally advanced or metastatic disease should be screened for hepatic dysfunction (Stauffer syndrome) and any associated coagulopathy. Patients' renal function can be evaluated by estimating the glomerular filtration rate (GFR) using the Modification of Diet in Renal Disease Study equation (Levey et al, 1999):

$$\text{GFR (mL/min/1.73 m}^2\text{)} = 186 \times (\text{SCr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if African-American})$$

Those in good health with two normally functioning kidneys are at low risk of requiring postoperative dialysis following open renal surgery; however, patients with GFR less than 60 mL/min or significant proteinuria are at increased risk of requiring dialysis. As a result, perioperative consultation with a nephrologist can be most useful in optimizing a patient's renal function pre- and postoperatively.

Assessment of cardiac and pulmonary status is important prior to any surgery, but because of the potential for significant cardiopulmonary compromise resulting from intraoperative positioning,

potential for blood loss, and possible fluid shifts, particular care needs to be taken to maximize cardiopulmonary function preoperatively (Fleisher et al, 2007a, 2007b).

In the modern era, cross-sectional imaging is a necessary step prior to any renal surgery (Bradley et al, 2011). Computed tomography (CT) and/or magnetic resonance imaging (MRI) studies are useful for proper surgical planning and assessment of renal parenchyma, renal pelvis and ureter, and renal vasculature (Fig. 60-1) (Derweesh et al, 2003; Herts, 2005).

Renal artery embolization (RAE) has been employed for palliation of inoperable renal tumors in order to control bleeding for large locally advanced renal tumors (Fig. 60-2 on the Expert Consult website) (Klimberg et al, 1985). In addition, RAE has been utilized to aid in surgical dissection of large renal tumors (Wszolek et al, 2008). Possible benefits of RAE prior to nephrectomy include shrinkage of an arterialized tumor thrombus to ease surgical removal, reduced blood loss, facilitation of dissection as a result of tissue plane edema, and ability to ligate the renal vein before the renal artery. However, because postinfarction syndrome, which includes flank pain, nausea, and fever, occurs in approximately three fourths of patients, RAE is not utilized by all surgeons, and in some retrospective series RAE is associated with high blood loss, possibly secondary to the increased edema associated with the infarcted renal tissue (Schwartz et al, 2007).

Surgical site infection can be minimized by following the American Urological Association's guidelines (Wolf et al, 2008). A single dose of cefazolin or clindamycin for patients undergoing renal surgery with negative urine culture is prescribed. Any active urinary tract infection should be treated preoperatively.

Prophylactic Measures

Mechanical bowel preparation is not indicated for open renal surgery unless there is concern about intestinal involvement of a pathologic process or iatrogenic intestinal trauma is likely because of multiple prior abdominal surgeries, with likely requirement of extensive lysis of adhesions. When bowel preparation is utilized, potential adverse effects need to be taken into consideration, including chronic renal deficiency particularly in older adult individuals (Heher et al, 2008). For renal surgeries that may require long postoperative care and management in the intensive care unit, prophylaxis with proton pump inhibitors or sucralfate has been shown to reduce gastric stress ulcers (Bredenoord et al, 2013).

While there is little evidence to support the use of thromboembolic prophylaxis for renal surgery, extrapolation from other similar surgeries suggests that routine use of intermittent pneumatic compression devices is useful to reduce the risk of

Figure 60-2. A, Aortogram in a patient with a left hypervascular renal mass. Note the pooling of contrast medium in the upper pole. B, Left selective artery angiogram before coil placement. C, Aortogram after coil placement demonstrating abrupt cutoff of flow from the left renal artery.

Figure 60-1. A, Preoperative computed tomography imaging demonstrates a large (4-cm) hilar lesion during a noncontrast film in a patient with a history of von Hippel-Lindau disease. B, Contrast administration demonstrates enhancement of a large intrarenal mass and nearby simple cyst. C, Delayed images depict close proximity to collecting system.

postoperative deep venous thrombosis. The American College of Chest Physicians advises pharmacologic therapy once the bleeding risk has diminished (Geerts et al, 2008). The American Urological Association recommends use of mechanical prophylaxis in all patients undergoing open surgery and consideration of pharmacologic prophylaxis in patients with elevated risk for deep venous thrombosis.

For cigarette smokers who are anticipating elective open renal surgery, if time permits, a 4- to 6-week preoperative smoking cessation program has been shown to reduce postoperative complications. Other strategies to reduce postoperative respiratory complications include the use of incentive spirometry in high-risk patients or simply deep breathing exercises in low-risk individuals (Overend et al, 2001).

Surgical Instruments

Self-retaining retractors (Omni-Tract, Omni-Tract Surgical, St. Paul, MN; Bookwalter, Codman & Shurtleff, Raynham, MA; or Balfour, Sklar Surgical Instruments, West Chester, PA), long genitourinary surgical instruments, bulldog and/or Satinsky vascular pedicle clamps, surgical clips, and a suction drain are common instruments available and used for most open renal surgeries.

SURGICAL APPROACHES

Adequate exposure is the hallmark of effective open renal surgery. Anatomic knowledge and consideration of adjacent visceral organs during the surgical approach are critical for safe surgical management. For right kidney surgery, the liver, colon, and duodenum serve as critical landmark structures, and for left kidney surgery, the spleen, tail of the pancreas, and colon need to be heeded. Proper incision and exposure minimize the amount of required retraction and minimize the likelihood of retractor-related injuries. The ideal surgical approach is one that is tailored not only to the operation being performed but also to the anatomy as defined on preoperative imaging, previous surgical history, body habitus, and presence of limiting factors such as kyphoscoliosis or pulmonary disease (Wotkowicz and Libertino, 2007).

Flank Approaches

For a flank incision, with the patient in the lateral decubitus position, the table is flexed between the iliac crest and costal margin. With the kidney bar raised, the structures of the retroperitoneum are better exposed; however, care needs to be taken to avoid injury to a previously repaired contralateral kidney.

Flank approaches may not be ideal in patients with preexisting cardiopulmonary deficits because exaggerated lateral decubitus positioning may compromise pulmonary function and venous return to the heart. In patients with severe kyphosis, the flank approach may not allow proper exposure of the retroperitoneum and may lead to unanticipated pressure on the flank and vertebral bones. Therefore, the surgeon needs to be familiar with other approaches and tailor the incision for each individual case.

Subcostal Flank Approach

The subcostal approach provides excellent exposure to the proximal ureter and renal parenchyma. It is well suited for approaches to the lower renal pole, ureteropelvic junction, and proximal ureter. However, access to the renal hilum is poor, making the subcostal approach somewhat limiting for management of large renal masses. In addition, it is not an ideal approach for partial nephrectomy, since excellent exposure and access to the renal hilum are required (Fig. 60-3).

After induction of anesthesia, insertion of an endotracheal tube, and introduction of a Foley catheter into the urinary bladder to monitor urine output, the patient is placed in the lateral decubitus position. The head is supported to avoid excess flexion at the cervical spine. A kidney bar can be employed if necessary; the tip of the 12th rib should be positioned over the kidney bar (Fig. 60-4 on the Expert Consult website). The patient's back is supported by a rolled blanket or surgical beanbag. To preserve stability and prevent forward roll, the dependent leg is flexed at the hip and knee and the top leg is kept straight. A pillow is placed between the knees. An axillary roll is deployed just caudal to the axilla to prevent compression or injury of the axillary neurovascular bundle. Other pressure points, including the upper foot, are padded with foam. The nondependent arm should be placed on a padded Mayo stand so that the arm is horizontal with slight forward rotation at the shoulder. The bed is flexed until the flank muscles are under stretch. The bed is placed in Trendelenburg position so that the flank is rendered parallel to the floor. The patient is secured to the mobile part of the operating table with 2-inch-wide adhesive tape, which fixes the patient in place while allowing adjustment of flexion.

After sterile preparation and draping, the skin incision begins at the costovertebral angle, approximately at the lateral border of the sacrospinalis muscle just inferior to the 12th rib. The incision is made a fingerbreadth below and parallel to the 12th rib and is carried onto the anterior abdominal wall. In an attempt to avoid the subcostal nerve, the incision can be curved gently downward at

the midaxillary line. If needed, the incision can be extended caudally or medially to the lateral border of the rectus abdominis.

The incision is carried sharply through the subcutaneous tissue, exposing the fascia of the latissimus dorsi and external oblique muscles. Electrocautery is used to incise the muscles in the line of the incision, starting with the latissimus dorsi posteriorly (Fig. 60-5 on the Expert Consult website). The posterior inferior serratus muscles, which insert into the lower four ribs, are also encountered in the posterior portion of the wound and transected. In the anterior aspect of the wound the external oblique muscle is divided. These maneuvers expose the fused lumbodorsal fascia, which gives rise to the internal oblique and transversus abdominis muscles. The lumbodorsal fascia and internal oblique muscle are divided (Fig. 60-6). By using two fingers inserted into an opening created in the lumbodorsal fascia at the tip of the 12th rib, the peritoneum is swept medially as the transversus abdominis is split digitally. The subcostal nerve should be identified between the internal oblique and transversus abdominis muscles and spared (Figs. 60-7 and 60-8).

Figure 60-5. Superficial incision through flank. (From Libertino JA, editor. *Reconstructive urologic surgery*. 3rd ed. Philadelphia: Mosby; 1998.)

Figure 60-8. The lumbodorsal fascia and transverse abdominal muscle have been divided to expose the Gerota fascia. The subcostal nerve and vessels pierce the lumbodorsal fascia posteriorly and course forward on the transverse abdominal muscle.

To maximize exposure in the posterior aspect of the incision, one may incise the posterior angle of the lumbodorsal fascia, exposing the sacrospinalis and quadratus lumborum muscles. Dividing the costovertebral ligament permits superior retraction of the 12th rib if enhanced exposure is deemed necessary. A Bookwalter flank retractor is used for exposure.

Supracostal Flank Approach

The supracostal flank incision (above the 11th or 12th rib) is favored by many open renal surgeons. An extraperitoneal, extrapleural approach can potentially minimize postoperative complications and lead to a more rapid recovery. [Turner Warwick \(1965\)](#), who popularized the approach, believed that the supracostal approach provides maximal posterior exposure, simplifies wound closure, and is less morbid than a transcostal incision requiring rib resection. More recently, an 8-cm modified mini-flank supra-11th rib incision has been described as a safe, effective approach to radical or partial nephrectomy for renal cortical tumors ([Diblasio et al, 2006](#)).

The level of the incision is determined by the patient's anatomy, the location of the lesion, and the planned procedure. Positioning is similar to that described for the subcostal flank approach.

A skin incision at the superior aspect of the 12th or 11th rib is made, beginning at the lateral border of the sacrospinalis muscle and continuing until the lateral border of the ipsilateral rectus abdominis muscle. The incision is carried through the subcutaneous tissue. The latissimus dorsi and posterior inferior serratus muscles are transected in the posterior aspect of the wound, revealing the intercostal muscles.

The external and internal oblique muscles are divided. The lumbodorsal fascia is opened at the tip of the rib to avoid both peritoneum and pleura. Moving medially, the transversus abdominis muscle is divided carefully while sweeping the peritoneum medially and inferiorly. The diaphragm is exposed by transection of the transversalis muscle. The pleura is identified between the divided transversus abdominis muscle and the diaphragm and can be mobilized superiorly.

The lateral aspect of the sacrospinalis is identified and is either incised or retracted to permit access to the neck of the rib and its attachments. Division of the intercostal muscles should start at the most distal aspect of the rib and proceed toward the spine. The corresponding intercostal nerve is identified and spared. To avoid the neurovascular bundle, the intercostal muscles are divided in

close proximity to the superior aspect of the rib. The plane between the chest wall and pleura is developed by entering the investing fascia surrounding the intercostal nerve, which allows an extrapleural dissection ([Fig. 60-9](#) on the Expert Consult website). The slips of the diaphragm attached to the inferior ribs are transected.

Dorsal Lumbotomy Approach

This approach is typically reserved for pediatric patients and for thin adults requiring bilateral nephrectomy. The advantage to this approach is low morbidity, since no muscle is transected. The main disadvantage is lack of exposure, particularly to the renal hilum and its vessels, making this approach very challenging particularly for obese and muscular individuals and patients with high-riding enlarged kidneys ([Andaloro and Lilien, 1975](#); [Gardiner et al, 1979](#); [Novick, 1980](#)).

The patient is first anesthetized and intubated in the supine position. The patient is then rolled into the prone position (ventral decubitus/ventral recumbent position) with the help of several operating room personnel and the operating table is flexed approximately 10 degrees. The arms may be tucked inward or positioned and supported cranially in an overhead swimming position. To protect the face and endotracheal tube, a C-shaped face support or doughnut-shaped foam pad may be used. The head can be rotated sideways or face downward. Eyes and ears are appropriately padded. To avoid axillary plexus injury, the humerus should not be forced into the axilla. The elbow should be flexed approximately 90 degrees and padded to prevent ulnar nerve injury. The knees should be padded and, to avoid pressure injury to the toes, the ankles should be supported and raised so that the toes do not touch the operating table. If necessary, the breasts should be displaced medially and cranially. Women who are pregnant or lactating, have breast implants, are obese, or have enlarged breasts are at risk of trauma to their breasts. The penis and scrotum should not be compressed by the body weight. In cases in which there are bowel/urinary abdominal stomas, extreme care should be taken to avoid excess pressure on these structures. In such cases, longitudinal torso frames/rolls should be used to minimize pressure from the anterior chest/abdominal structures.

The prone position may be poorly tolerated by older adults, patients with cervical spine pathology, patients with unstable chest walls following trauma, and patients with a known thoracic outlet syndrome. From a cardiovascular standpoint, the thoracic outlet syndrome (resulting from an anomalous cervical rib or some other anatomic reason) can occur particularly when the arms are located in the swimmer's position and the head is turned to one side. Because of increased pressure on the sternum, unanticipated pressure may be generated on the mediastinum, reducing coronary blood flow. Hemodynamically, the central venous pressure may rise, resulting in venous engorgement and potentially increased bleeding. From a respiratory standpoint, an increased amount of work is required to breathe when prone, an endotracheal tube can be displaced accidentally, and the risk of venous air embolism from central lines is increased. From a neurologic standpoint, rotation of the head can modify the cerebral blood flow and place the patient at risk of cerebral ischemia.

The dorsal lumbotomy approach is an anatomic approach to the kidney, with incision of fascial planes rather than muscle ([Fig. 60-10](#)). A vertical skin incision is made from the inferior border of the 12th rib to the iliac crest, in line with the lateral border of the sacrospinalis muscle. The subcutaneous tissues are divided, exposing the latissimus dorsi muscle. The aponeurosis of the latissimus dorsi is separated from the posterior layer of the lumbodorsal fascia where it overlies the sacrospinalis muscle. The posterior layer of the lumbodorsal fascia, a strong fascial covering, is incised, which allows the sacrospinalis muscle to be retracted medially. The costovertebral ligament is divided, which permits superolateral retraction of the 12th rib, which improves access superiorly. The fused middle and anterior layers of the lumbodorsal fascia are divided, permitting the quadratus lumborum muscle to be retracted medially. The ilio-inguinal nerve should be identified and spared. Entry into the

Figure 60-10. Cross-sectional view of Gil-Vernet approach. (From Libertino JA, editor. *Reconstructive urologic surgery*. 3rd ed. Philadelphia: Mosby; 1998.)

Figure 60-11. Thoracoabdominal incision at the supra-10th rib border with patient in lateral decubitus position.

paranephric space is achieved by incising the transversalis fascia. Division of the perinephric fascia reveals the kidney.

Thoracoabdominal Approach

The thoracoabdominal approach (Fig. 60-11) is ideal for the management of large renal masses, suprarenal or upper pole masses, renal tumors with venous extension, and tumors involving adjacent structures.

The patient is positioned in a semioblique manner as described above for the flank approaches, with a rolled blanket or beanbag supporting the flank. The legs are positioned similar to the traditional flank position. The pelvis is rotated to a more horizontal position than for the flank incisions, at an angle of approximately 45 degrees.

The level of the incision is determined by the nature of the tumor, including size and relationship to surrounding structures. Depending on the location of the tumor, access is gained through the 8th, 9th, 10th, or 11th intercostal spaces. The skin incision begins at the lateral aspect of the sacrospinalis muscle over the 10th or 11th rib and can travel as far as the contralateral rectus abdominis muscle or caudally toward the symphysis pubis.

The internal oblique and transversus abdominis muscles are transected. The underlying peritoneum is opened, and the peritoneal cavity and chest are entered. Staying close to the superior

Figure 60-14. The white line of Toldt is incised from the hepatic flexure to the common iliac artery and the ascending colon is reflected medially. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

border of the rib, the intercostal muscles are divided, which exposes the underlying pleura and diaphragm. The pleura is opened sharply, taking care to avoid the lung. The costovertebral ligament is divided. The diaphragm is opened from its thoracic surface. Starting anteriorly and proceeding posteriorly, the diaphragm is opened in a curvilinear fashion staying about two fingerbreadths from the chest wall to avoid injuring the more central phrenic nerve.

The liver or spleen is gently retracted upward. Additional hepatic mobility can be obtained by dividing the coronary ligament and the right triangular ligament of the liver (Fig. 60-12; Fig. 60-13 on the Expert Consult website). For right-sided tumors, the kidney and great vessels are approached by mobilizing the colon medially and Kocherizing the duodenum (Figs. 60-14 and 60-15 on the Expert Consult website; Fig. 60-16). For tumors on the left, the colon and

Figure 60-16. Access to the vena cava can be achieved using the Langenbeck maneuver whereby the right triangular and coronary ligaments of the liver are divided, permitting the right lobe of the liver to be rotated medially and cephalad, exposing the retrohepatic inferior vena cava up to the diaphragms. (© The Lahey Clinic.)

the tail of the pancreas are mobilized (Fig. 60-17 on the Expert Consult website; Fig. 60-18).

Anterior Approaches

Anterior Midline Approach

An anterior midline incision is the incision of choice for management of renal trauma because it permits exploration for associated intraperitoneal injuries. It can also be employed for renovascular surgery, for reconstructive procedures, including ileal ureteral replacement, and for bilateral renal procedures.

With the patient in the supine position, a midline skin incision is carried out between the xiphoid process and the symphysis pubis. After dividing the subcutaneous tissues with electrocautery, the linea alba is sharply incised to expose the underlying preperitoneal fat and peritoneum. The peritoneum is grasped with two smooth forceps and incised. The ligamentum teres should be divided and suture ligated.

Control of the renal pedicle can be obtained directly through the posterior parietal peritoneum or by medial reflection of the colon. On the left, the approach involves a vertical incision in the posterior peritoneum below the ligament of Treitz. This space contains the anterior surface of the aorta, the crossing left renal vein, and often the inferior mesenteric vein and gonadal vessels. The superior mesenteric artery should be on the anterior surface of the aorta and is usually 1 to 2 cm cephalad to the left renal vein. Gentle dissection along the hilum at this level provides good vascular control. A second approach to the left renal hilum is through the lesser sac. In this approach, the gastrocolic omentum is divided and entered. The transverse colon can then be retracted inferiorly. The peritoneum below the pancreas can be incised. The vessels are identified. This permits access to the renal pedicle both anteriorly and posteriorly. The artery can be isolated posteriorly and the venous system identified and controlled anteriorly.

Similarly, the right kidney can be reached directly by incision of the hepatic flexure and a Kocher maneuver to free the duodenum

Figure 60-18. A, Left gastrocolic, phrenocolic, and lateral peritoneal attachments are divided. B, Stomach, pancreas, and spleen are gently retracted upward without mobilizing the kidney. (© The Lahey Clinic.)

and reflect it medially. Further incision along the white line of Toldt frees the colon, permitting exposure of the anterior Gerota fascia. After the duodenum is reflected, the anterior surface of the vena cava is exposed. Care is taken not to injure the pancreas, gonadal vein, adrenal vein, or accessory renal vessels. The main renal vein is mobilized. Posterior to the renal vein along its superior margin lies the renal artery (Fig. 60-19 on the Expert Consult website), which normally runs a retrocaval course. The renal artery can be isolated here or between the vena cava and aorta when greater length is required.

Anterior Subcostal Approach

For the anterior subcostal approach, the patient is placed in the supine position. Some surgeons choose to place a rolled blanket underneath the lumbar spine in order to facilitate exposure with hyperlordosis. However, **excessive hyperlordosis can lead to excessive unwanted tension on the great vessels, minimizing blood flow. Also, excessive hyperlordosis may lead to postoperative lower back pain. In patients with spinal stenosis, hyperlordosis is not recommended.** In the supine position, the arms can be tucked at the side or abducted at 90 degrees while supported on arm pads. The elbows should be well protected with adequate padding to avoid ulnar nerve injury.

The supine position can cause several important problems; therefore care should be taken to avoid complications from positioning. The pressure points (occiput, dorsal torso, sacrum, dorsal legs, and heels) should be well padded. From a cardiovascular perspective, supine positioning can result in supine hypotension (aortocaval syndrome) if excess adiposity or abdominal masses compress the great vessels. From a musculoskeletal perspective, low back pain is frequent, particularly in those patients with scoliotic and kyphotic spine deformities. Artificial hip and knee joints may also be placed under stress.

Chevron Incision (Bilateral Anterior Subcostal Approach)

The chevron incision, which is composed of bilateral anterior subcostal incisions, is ideal for renovascular surgery and radical

Figure 60-17. For left-sided tumors, the white line of Toldt is incised from the splenic flexure to the common iliac artery and the descending colon is reflected medially. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

nephrectomy with inferior vena cava (IVC) tumor thrombectomy. Exposure of the renal pedicles and great vessels is outstanding. The incision starts at the tip of the 11th rib, extends approximately two fingerbreadths below and parallel to the costal margin, curves superiorly in the midline, travels parallel to the contralateral costal margin, and terminates at the tip of the contralateral 11th rib.

SURGERY FOR BENIGN DISEASES

Simple Nephrectomy

Simple nephrectomy—removal of the kidney within the Gerota fascia—is used to manage nonmalignant diseases of the kidney (Fig. 60-20 on the Expert Consult website). Indications for simple nephrectomy include durable nonfunction or poor function of a kidney as a result of obstruction, infection, trauma, stones, nephrosclerosis, vesicoureteral reflux, polycystic kidney, or congenital dysplasia. Simple nephrectomy of a functional kidney may be employed to relieve intractable symptoms or associated problems, such as bleeding, pain, hypertension, or persistent infection.

Using one of the incisions described above, typically a flank incision, access to the retroperitoneal cavity is obtained. A self-retaining retractor (Finochietto, Bookwalter, or Omni-Tract retractor) is used to expose the visceral organs. The posterior layer of the renal fascia is bluntly dissected from the muscles of the posterior abdominal wall. The anterior layer of renal fascia is dissected from the colonic mesentery and peritoneum, leaving a fascial compartment in which the kidney, adrenal gland, and perirenal fat lie. The renal fascia is incised and the perirenal fat is separated from the kidney using a combination of blunt dissection and electrocautery. Improper entry into the subrenal capsule must be avoided as this can lead to additional bleeding and difficulty in identifying the appropriate surgical planes. The surgeon must beware of aberrant vessels, typically found near the poles and in areas resistant to blunt dissection. In cases in which posterior dissection is difficult because of adherence of the kidney to the psoas muscle, inclusion of the psoas fascia in the dissection may be helpful and necessary. In cases of a large hydronephrotic kidney, in which exposure can be difficult, puncture and aspiration of the renal pelvic contents may decompress and aid mobilization of the kidney. Next, the adrenal gland is dissected from the upper pole of the kidney by maintaining the dissection plane directly on the renal capsule. The superior attachments of the kidney to the spleen, pancreas, and liver are freed to allow safe caudal retraction of the kidney.

Next, the lower pole of the kidney is mobilized and the ureter isolated, and the gonadal vein, usually found adjacent to the ureter, is identified. Care should be taken to mobilize the gonadal vein medially in order to avoid traction injury and avulsion of the vein. Once the inferior pole is mobilized, the ureter can be divided in between surgical clips or 2-0 silk ties. Division of the ureter provides access to the posterior part of the kidney and better exposure of the

renal hilar structures. From a caudocranial approach, the renal vein is usually identified after division of the ureter. Combination of blunt and sharp dissections will allow identification of the renal artery posterior to the renal vein (Fig. 60-21).

Partial Nephrectomy for Benign Disease

Partial nephrectomy, in addition to its common utilization for treatment of small-sized renal cancer, can sometime be used for benign diseases. Some clinical scenarios in which partial nephrectomy may be indicated in benign diseases include hydronephrosis with parenchymal atrophy, atrophic pyelonephritis in a duplicated kidney, infected calyceal diverticulum, segmental traumatic renal injury with irreversible damage, and removal of benign renal tumors (angiomyolipoma or oncocytoma).

Partial nephrectomy for benign disease entities can be approached by excision of the renal capsule from the diseased site. The excised renal capsule can be successfully used for renorrhaphy (Fig. 60-22). Further details and techniques of partial nephrectomy are described in the section on surgery for malignant disease.

Open Nephrostomy

With the advancement in percutaneous nephrostomy tube placements, open surgical insertion of nephrostomy tubes is rare. However, when percutaneous nephrostomy tube placement is not technically feasible and endoscopic placement of a ureteral stent is not an option, open surgical placement of a nephrostomy tube can be a lifesaving procedure (Fig. 60-23 on the Expert Consult website).

Through a retroperitoneal flank incision the Gerota fascia is identified and incised. The kidney is mobilized within the Gerota fascia to expose the posterior surface, and the ureter is identified inferiorly. The ureter is followed superiorly in order to identify the renal pelvis. The renal pelvis is incised after placement of two 2-0 absorbable Vicryl (Ethicon, Cincinnati, OH) holding sutures away from the ureteropelvic junction. Using a hooked scalpel or sharp tenotomy scissors, a 2-cm incision is made parallel to the long axis of the kidney between the holding sutures. Next, a stone forceps is passed through the pyelotomy incision into the lower pole calyx. The tip of the forceps is aimed at the convex border of the kidney, because a nephrostomy on the anterior or posterior surface of the kidney has a higher risk of hemorrhage from damage to intrarenal vessels. While pressure is applied with the forceps, the tip of the forceps is palpated at the convex border of the kidney. A radial capsulotomy is made over the tip of the forceps. The tract through the parenchyma is widened. From the exterior surface of the kidney a Malecot catheter with a threaded 0 silk suture at the tip is guided through the renal parenchyma; the tip is placed in the renal pelvis and the guiding 0 silk suture is removed. The Malecot catheter is secured to the renal capsule using a 3-0 absorbable purse-string suture, and the pyelotomy is closed with 4-0 Vicryl sutures and the

holding sutures are removed. The distal end of the Malecot catheter is externalized through a stab incision from the anterior flank, avoiding kinking of the tube to ensure proper drainage. The Malecot catheter is secured to the skin externally using a drain stitch (2-0 silk or 3-0 nylon). A Penrose drain or Jackson-Pratt drain (Cardinal Health, Dublin, OH) is placed in the perinephric area and the flank incision is closed.

Extracorporeal Renal Surgery

Extracorporeal renal surgery (ECRS) with autotransplantation is an operative technique that is rarely used in contemporary urologic practice, since open *in situ* renal exposure with vascular clamping and hypothermia provides excellent access to the kidney for nearly all forms of renal surgery. The advantages of ECRS are better exposure and illumination, a bloodless surgical field, the ability to protect the kidney from prolonged ischemia, and the opportunity to use an operating microscope (Ota et al, 1967; Husberg et al, 1975; Putnam et al, 1975). Currently, ECRS is reserved for reconstruction of complex renal pathologies in cases of a solitary kidney, when percutaneous approaches are not appropriate or possible, and when routine *in situ* operative exposure is inadequate (Fig. 60-24). Additionally, ECRS is used when addressing anatomic problems in a donated kidney that is destined for allogeneic transplantation.

Specific indications for which ECRS may be a valid option are listed below:

Renovascular diseases

- Prolonged ischemia (>45 minutes) is anticipated
- Segmental renal artery disease
- Multivessel disease
- Arteriovenous malformations refractory to embolization
- Large intrarenal arterial aneurysms

Renal transplantation

- Repair of vascular anomaly
- Repair of collecting system anomaly

Malignancy in solitary kidney

- Large, central mass encroaching on the renal pelvis
- Large, central renal pelvic tumor
- Multiple subcortical neoplasms

Preoperative Considerations

Thorough abdominal imaging studies (CT scan and/or magnetic resonance angiogram) should be obtained to fully evaluate the renal parenchyma, collecting system, and vasculature. In select cases, digital subtraction arteriography may be used to evaluate the vascular anatomy.

Figure 60-24. Extracorporeal renal surgery. A, Computed tomography (CT) scan demonstrating larger midpolar tumor in a solitary right kidney. B, Three-dimensional arterial reconstruction. C, Kidney on back table in hypothermic solution prior to tumor excision. D, Mass excised with preservation of collecting system and intrarenal arterial tree. E, Contrast-enhanced CT scan 4 years later demonstrating no evidence of recurrence.

The patient's renal function is assessed by serum creatinine level. Strong consideration should be given to obtaining a preoperative nephrology consultation to help maximize renal function preoperatively and to make necessary preparations in case of hemodialysis postoperatively.

A seated operative bench should be available with ice slush, renal transplant preservation solution (e.g., Euro-Collins or UW solution), and microvascular instruments.

Surgical Procedure

Since access to both the retroperitoneum and iliac fossa (for autotransplantation) is required, a number of different single- or double-incision approaches are possible. Following incision and abdominal exploration, the kidney is exposed as for a living related donor nephrectomy. When the kidney is mobilized and the only remaining attachments are the ureter, renal vein, and renal artery, 12.5 g of mannitol and 20 mg of furosemide are rapidly infused intravenously. The ureter is ligated as far distally as possible and transected, preserving as much periureteral tissue as possible. Although the ureter can be preserved intact, we do not favor this approach since it limits positioning the autotransplanted kidney in the opposite iliac fossa, and the long length of ureter is prone to ischemia and kinking leading to obstruction. Vascular clamps are applied to each renal vessel directly where they exit the aorta and IVC (a C-shaped clamp is useful to gain length on the right renal vein) and the renal vessels are transected directly on the clamps.

Immediately after dividing the renal vessels, the kidney is placed on the workbench in a pan of ice slush covered with a towel. The kidney is flushed intra-arterially by gravity flow with renal preservation solution at 6° C. Flushing the kidney should continue until it is cooled and the renal effluent is clear (~500 to 1000 mL). The kidney is kept in the ice slush basin during the procedure to maintain hypothermia.

For renovascular disease, the vasculature of the renal hilum is dissected and vascular repair is done. For neoplasms, the Gerota fascia and the perirenal fat are removed and partial nephrectomy is undertaken. After reconstruction of the renal vasculature or the nephrectomy parenchymal defect is achieved, the renal artery and vein are flushed independently with preservation solution to assess for potential sites of bleeding. Retrograde flushing of the ureter is done to assess for collecting system leaks, which should be repaired if identified.

The kidney may be transplanted into either lower quadrant. The kidney is transferred to the iliac fossa, and the renal vein is anastomosed to the external iliac vein. The renal artery anastomosis can be achieved by either end-to-end anastomosis to the hypogastric artery or end-to-side anastomosis with the external iliac artery.

During the anastomosis, the vessels should be irrigated with heparin solution (10,000 units of heparin in 100 mL of normal saline), and the surgeon should consider injecting 10 mg of verapamil into the renal artery following the anastomosis to help vasodilation. The ureter is implanted into the dome of the bladder with a tension-free anastomosis. Prior to completion of the ureteral anastomosis, a ureteral stent is placed. Finally, a closed suction drain is placed.

SURGERY FOR MALIGNANCY

Radical Nephrectomy

Radical nephrectomy refers to complete removal of the kidney outside the Gerota fascia together with the ipsilateral adrenal gland and complete regional lymphadenectomy from the crus of the diaphragm to the aortic bifurcation as described by [Robson and colleagues in 1969](#) for management of renal malignancy. Today, the adrenal gland is typically spared when technically possible, since removal of the adrenal gland, when not involved by tumor, has not been shown to improve survival of patients with renal cancer. Extensive lymphadenectomy is only done in select cases when it is strongly felt that it may contribute to improved patient survival without adding complications to patient's recovery.

Radical nephrectomy is reserved for renal tumors that are not amenable to partial nephrectomy. Indications for radical nephrectomy include tumors in nonfunctional kidneys, large tumors replacing the majority of renal parenchyma, tumors associated with detectable regional lymphadenopathy, or tumors associated with renal vein thrombus.

All renal tumors suspicious of malignancy should be staged with abdominopelvic CT or MRI and chest imaging with chest x-ray or chest CT ([Fig. 60-25](#)) ([Bradley et al, 2011](#); [Chen and Uzzo, 2011](#)). If any sign of metastatic disease is present, a bone scan and head CT should also be obtained. The cross-sectional imaging should be closely evaluated for tumor thrombus, enlarged retroperitoneal nodes, and any embryologic abnormalities of the renal collecting system and vasculature.

Prior to surgery, percutaneous renal biopsy can be considered in patients with another malignancy to evaluate for potential metastatic disease, to evaluate for the possibility of lymphoma in cases of infiltrative-appearing renal masses on imaging studies and solid masses that will be managed nonoperatively with percutaneous modalities (radiofrequency or cryotherapy), or in nonoperative cases when the histology may dictate the type of systemic therapy ([Volpe et al, 2007](#); [Pandharipande et al, 2010](#); [Psutka et al, 2013](#)). In cases of bilateral renal tumors, percutaneous renal biopsy should be considered in order to guide management ([Blute et al, 2000](#)).

Figure 60-25. Axial (A) and coronal (B) magnetic resonance images of a right-sided renal mass.

Figure 60-26. A and B, Kocher maneuver. (From Smith JA Jr, Howards SS, Preminger GM, editors. *Hinman's atlas of urologic surgery*. 3rd ed. Philadelphia: Saunders; 2012.)

At times, preoperative angioembolization is undertaken for the kidney with a large renal mass and regional lymphadenopathy (Schwartz et al, 2007). Potentially, angioembolization can reduce the amount of intraoperative blood loss and provide the ability to ligate the renal vein before the renal artery, which may be necessary as a result of extensive hilar lymphadenopathy. Angioembolization may also reduce the size of the primary tumor, thereby technically improving the feasibility of nephrectomy. Disadvantages of angioembolization include postinfarction painful syndrome, risk of tumor lysis syndrome, risk of embolization of tumor thrombi, and risk of vascular trauma.

Ipsilateral adrenalectomy should be considered in large upper pole tumors when the surgical plane between the kidney and adrenal gland may be compromised. Otherwise, routine adrenalectomy is not required since the overall incidence of adrenal metastasis is less than 5%. Because preoperative CT and MRI may miss 20% to 25% of adrenal metastases, one must consider clinical indicators of adrenal involvement to guide surgical practice (Siemer et al, 2004). Typically, adrenalectomy would be indicated when there is diffuse involvement by tumor, large tumor size (>10 cm), extrarenal tumor extension, tumor thrombus, lymphadenopathy and regional metastasis, or an adrenal mass on imaging.

Regional lymphadenectomy is not required in every radical nephrectomy, since the overall incidence of lymph node disease is about 5%. Regional lymphadenectomy should be considered in those patients who may have a reasonable chance of benefiting from the added surgery. The probability of regional nodal involvement is discussed by Blute and coworkers (2004a) and Crispen and colleagues (2011). Indications for regional lymphadenectomy include enlarged lymph nodes on imaging, cytoreductive surgery for metastatic disease, tumor size greater than 10 cm, nuclear grade 3 or greater, sarcomatoid histology, presence of tumor necrosis on imaging, extrarenal tumor extension, and tumor thrombus and direct tumoral invasion of adjacent organs.

In cases of adjacent organ involvement (colon and/or spleen), preoperative planning for splenectomy and/or partial colectomy is important (Blute et al, 2004a). Owing to the presence of its bilaminar capsule, the liver is not usually directly invaded by renal tumors despite preoperative imaging studies that may suggest extension of right-sided renal tumors to the liver. However, in rare circumstances when a right-sided renal tumor does directly invade the liver, appropriate preoperative surgical planning is essential.

Surgical Procedure

The most commonly used incisions for radical nephrectomy are subcostal flank incisions, which are described above. In brief, for a subcostal approach, the patient is placed in a modified lateral decubitus position. After incising through the skin and muscular layers, a Balfour, Bookwalter, or Omni-Tract retractor is placed and, for a
